20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

This report describes in detail a two-dimensional computer model for the steady-state operation of an MOSFET, and is intended to serve as a USER'S MANUAL for that model. Detailed flow charts are included.

The model is shown to produce results in good agreement with those produced by a prototype model which is the proprietary property of IBM. It is also shown to agree well with experimental data obtained from a p-channel device whose parameters have been well characterized by means of test sites.

FOREWORD

Custom integrated semiconductor circuits are often needed for military applications that involve a vast number of different, highly specialized, electronic systems, although seldom are these systems called for in large quantity. This combination produces an economically prohibitive situation. The large initial cost for designing integrated circuits, in conjunction with a small production requirement, creates an unreasonably large cost per IC chip. The source of this difficulty lies in empirical, and costly, engineering techniques used during both IC design, and production start-up. Empirical techniques are used during IC design to solve problems for which there is inadequate basic understanding. Similar empirical techniques are also used during production start-up to overcome problems that presently cannot be solved by design engineers.

An important source of this problem lies in the lack of adequate models for the design and development of IC structures. This effort is part of the DARPA funded research, pursued to ARPA Order No. 2985, and is intended to replace the empirical and costly conventional engineering approach to IC development for military systems with a computed aided cost effective method. In particular, this report describes, in detail, a two-dimensional computer model for the steady-state operation of an MOSFET and is intended to serve as a USER's MANUAL for that model.

CHAPTER I

A Two-Dimensional Model for MOSFET Operation

1.0 Introduction

This report is an addendum to the Final Research and Development Technical Report under this contract on Computer Aided Engineering of Semiconductor Integrated Circuits, dated August 31, 1977. The present report presents further details concerning a two-dimensional mathematical model for an MOSFET, and is intended to serve as a USER's MANUAL for the computer program which has been developed to implement that model.

The model described herein is patterned from the earlier work of M.S. Mock who developed a two-dimensional MOSFET model for IBM [1-3]. This useful analytic tool, which has produced results in good agreement with experiment [4], was provided to us by IBM with the understanding that it would be regarded as their proprietary property. That computer program was utilized extensively in the development of a one-dimensional MOSFET model described in detail in Chapter I of the Final Report named above.

In order to make such a two-dimensional analytic tool available to government laboratories, and to the semiconductor industry, the development of the model reported herein was undertaken with the intention of disseminating the resultant computer program to those desiring it, accompanied by this USER's MANUAL.

---

[2] D.P. Kennedy, Mathematical Simulation of the Effects of Ionizing Radiation on Semiconductors, Scientific Report No. 1, AFCRL-71-0272 (1971).

[3] D.P. Kennedy, Mathematical Simulation of the Effects of Ionizing Radiation on Semiconductors, Final Report, AFCRL-72-0257 (1972).

[4] D.P. Kennedy, Private Communication.

It should be emphasized that the proprietary nature of the IBM program has been scrupulously observed during this development. Some of the algorithms implemented in our model are due to Mock, but only those which he has described in the literature [1-3]. No attempt has been made to copy the IBM program. We have, of course, made liberal use of that program as a means of providing numerical checks of the performance of our model. The availability of that program for this purpose is gratefully acknowledged.

2.0 Description of the Model

The computer model treats an n-channel enhancement mode MOSFET in which the conducting channel is formed by a gate-induced inversion layer just below the interface between a uniformly doped p-type substrate and the SiO_2 layer (hereinafter named the oxide) upon which the gate metallization is deposited. The inherent thinness of the inversion layer justifies the assumptions made that the net electron-hole recombination rate and the hole current are negligible in the steady state operation of this device. Details are given in the following subsections.

2.01 Basic Geometry

Figure 1(a) depicts such an n-channel device in which the source and drain consist of n^+ islands diffused into the p-substrate. The thinness of the gate-induced inversion layer of mobile electrons formed just below the oxide-silicon interface makes possible the adoption of the simplified rectangular geometry of Figure 1(b), wherein the vertical metallurgical p-n junctions (assumed to be abrupt transitions between p and n^+ regions) are located at the left and right borders of the rectangular region treated. Large gradients in electric potential and, consequently, in the electron and hole densities are expected in the immediate vicinity of those junctions, requiring a rather dense array of the geometric points at which those variables are calculated with the finite-difference equa-

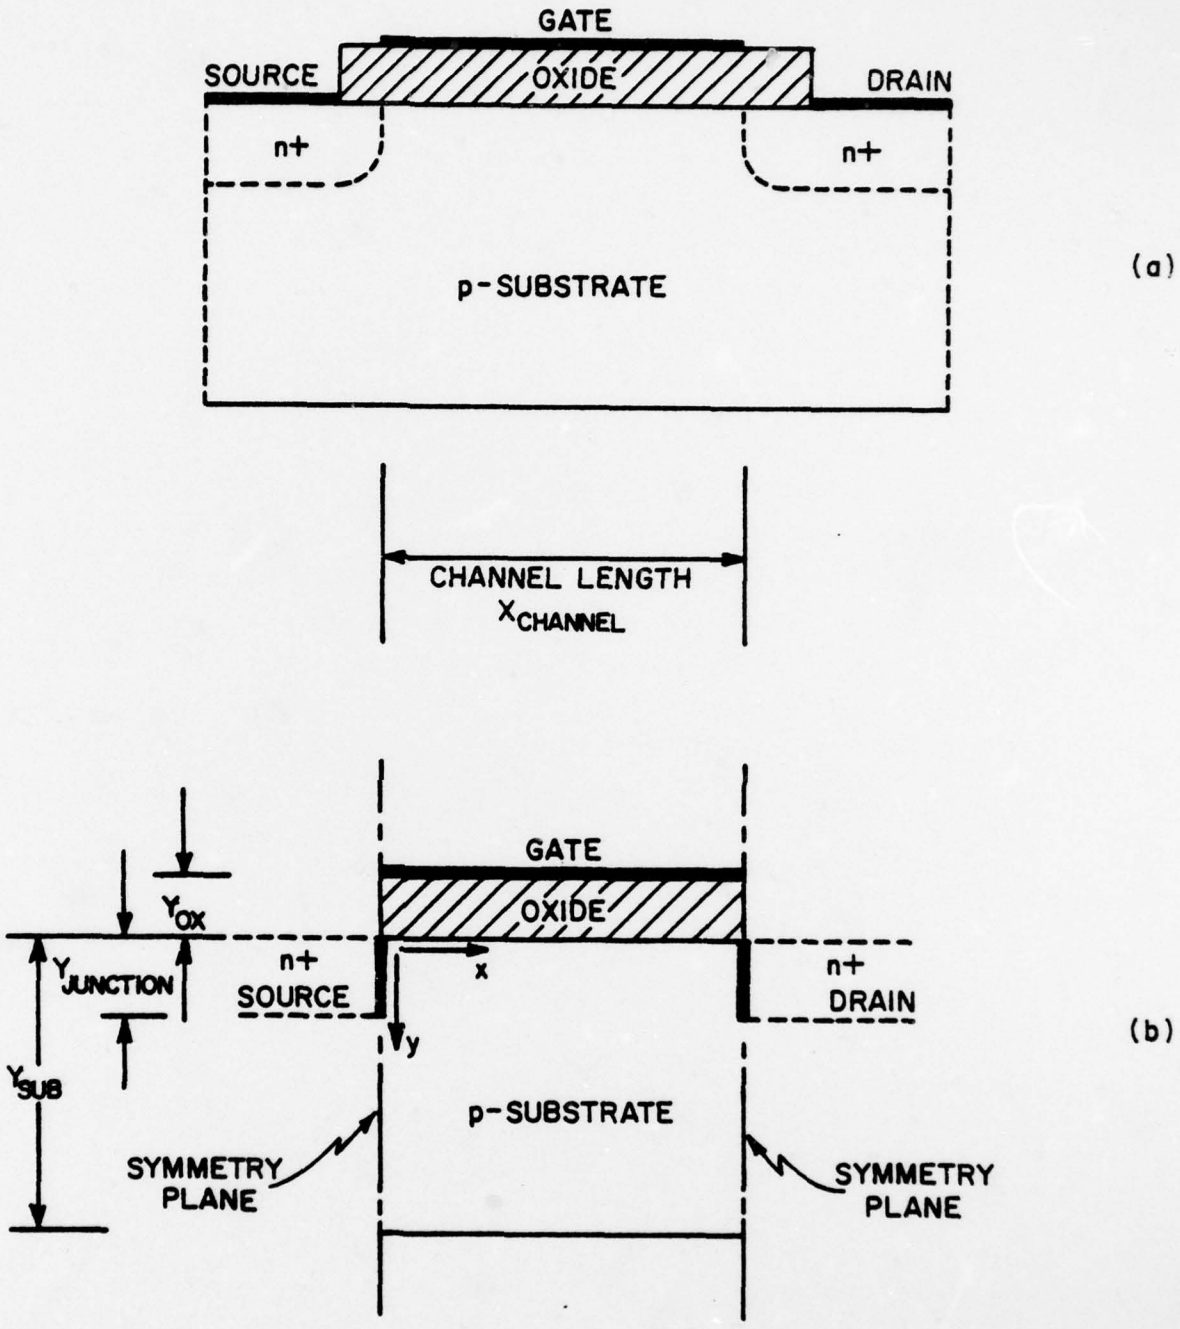

Figure 1 (a) Cross-section of an n-channel MOSFET.

(b) Rectangular region modeled. The abrupt metallurgical junctions between source-substrate and drain-substrate are regarded as planar and at the left and right borders of the region modeled.

tions employed. The same is true in the region just below the oxide-silicon interface where the inversion layer forms. On the other hand, the density of such points in regions remote from those surfaces can be relatively sparse. By placing the source and drain junctions at the borders of the rectangular region treated, such a graded lattice of points is readily defined. Figure 2 illustrates the graded lattice employed by the model with a 41 (horizontal) by 25 (vertical) array overlayed on the rectangle. The prescription adopted for generating this graded lattice is precisely that suggested by Mock [1].

2.02 Dimensionless Variables

For computational purposes, the adoption of dimensionless (normalized) variables at the outset results in two benefits: (1) unnecessary multiplications by redundant constants such as ε_o, q, kT/q, n_i, etc. can be precluded, and (2) numerical scaling causing most variables to lie within reasonable numerical ranges can be achieved.

Understanding that such dimensionless variables will be utilized in all of which follows (with few exceptions which will be clearly flagged), we shall designate physical variables (i.e., those which possess dimensions) in this subsection by means of primed symbols, using corresponding unprimed symbols for their dimensionless counterparts. This convention provides the advantage of utilizing conventional symbols such as $\bar{J}$ for current density, n and p for electron and hole densities, ψ for electric potential, etc., even though those variables are normalized. In this vein, the dimensionless variables employed in our model are defined in Table I.

2.03 Basic Equations

Having adopted the assumptions of negligible hole current and electron-hole recombination, the dimensionless equations describing the physical mechanisms within this semiconductor device are:

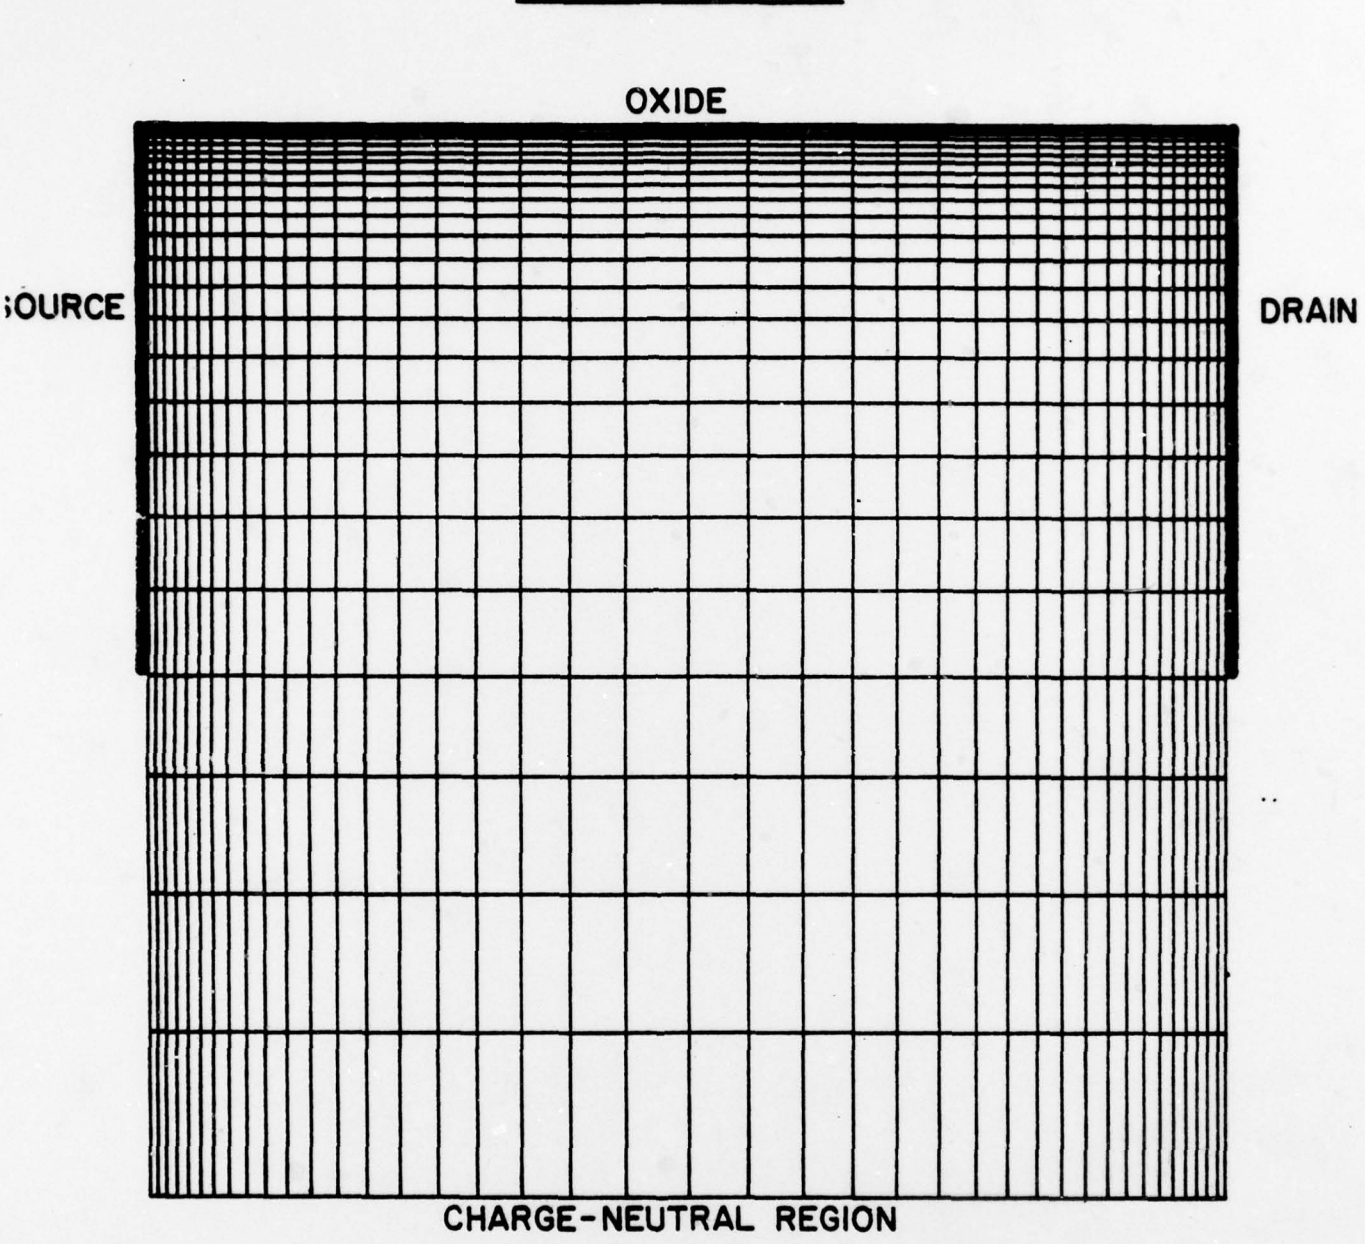

Figure 2 Graded lattice of points used in the finite-difference equations dealt with in the computer model.

TABLE I--DEFINITION OF DIMENSIONLESS VARIABLES
(κ_s is the relative permittivity of silicon)

Define:

$L_D' = \sqrt{\frac{\kappa_s \varepsilon_o' (k'T'/q')}{q' n_i'}}$	,	Intrinsic Debye length of silicon
μ_n'	,	Low field electron mobility

Then Let:

$\psi' = (k'T'/q')\psi$ $\phi_n' = (k'T'/q')\phi_n$ $\phi_p' = (k'T'/q')\phi_p$	,	Electric potential, and electron and hole quasi-Fermi potentials
$N_D' = n_i' N_D$ $N_A' = n_i' N_A$ $n' = n_i' n$ $p' = n_i' p$	,	Donor, acceptor, electron, and hole number densities
$x' = L_D' x$ $y' = L_D' y$	,	Cartesian coordinates
$\bar{J}' = \left[\frac{(k'T'/q')\mu_n' n_i' q'}{L_D'} \right] \bar{J}$	,	Electron current density
$Q_{ss}' = \left[\frac{(k'T'/q')\kappa_s \varepsilon_o'}{L_D'} \right] Q_{ss}$	,	Surface charge density
$\mu' = \mu_n' \mu$	,	Electron mobility

$$\nabla^2\psi = N_A + n - p \ , \tag{1}$$

$$n = \exp(\psi - \phi_n) \ , \tag{2}$$

$$p = \exp(\phi_p - \psi) \ , \tag{3}$$

$$\bar{J} = -\mu n \nabla\phi_n \ , \tag{4}$$

$$0 = \nabla\phi_p \ , \tag{5}$$

$$\nabla\cdot\bar{J} = 0 \ . \tag{6}$$

Equation (1) is Poisson's equation for the electric potential ψ, eqs. (2) and (3) express the use of Boltzmann statistics for the electron and hole number densities n and p (i.e., nondegenerate doping of the p-substrate is implied), eq. (4) relates the electron current density vector $\bar{J}$ to the electron quasi-Fermi potential ϕ_n and number density n in the usual manner [5], eq. (5) enforces zero hole current density, while eq. (6) assures conservation of charge under the assumed condition of zero net recombination of electron-hole pairs.

The above equations apply only in the rectangular p-substrate region. The conditions in the oxide are described by:

$$\nabla^2\psi = 0 \ , \tag{7}$$

and $n = p = \bar{J} \equiv 0$, with appropriate boundary conditions to match the tangential and normal electric field at the oxide-silicon interface.

The divergence-free flow of electron current expressed by (6) can be enforced by introducing a stream function $\theta(x,y)$, as did Mock, such that the x and y components of $\bar{J}$ are given by:

$$J_x = J_o \frac{\partial\theta}{\partial y} \ , \tag{8}$$

$$J_y = -J_o \frac{\partial\theta}{\partial x} \ , \tag{9}$$

---

[5] S.M. Sze, Physics of Semiconductor Devices, p. 96, Wiley, N.Y. (1969).

thereby assuring that $\nabla \cdot \bar{J} = 0$. Here, J_o is a scalar constant whose determination will be discussed later. We next seek the differential equation which must be satisfied by this stream function.

Solving (2) for the electron quasi-Fermi potential ϕ_n, and substituting the result into (4), we obtain:

$$\bar{J} = \mu e^{\psi} \nabla (n e^{-\psi}) \ . \tag{10}$$

Identifying the x and y components of (10) with the corresponding expressions of (8) and (9), we have:

$$J_o \frac{\partial \theta}{\partial y} = \mu e^{\psi} \frac{\partial}{\partial x} (n e^{-\psi}) \ , \tag{11}$$

$$J_o \frac{\partial \theta}{\partial x} = -\mu e^{\psi} \frac{\partial}{\partial y} (n e^{-\psi}) \ . \tag{12}$$

Divide both sides of these intermediate equations by μe^{ψ}, then differentiate the first partially with respect to y, the second partially with respect to x, and add the two, obtaining:

$$\frac{\partial}{\partial x} \left(\mu^{-1} e^{-\psi} \frac{\partial \theta}{\partial x} \right) + \frac{\partial}{\partial y} \left(\mu^{-1} e^{-\psi} \frac{\partial \theta}{\partial y} \right) = 0 \ . \tag{13}$$

Eq. (13) is a second order differential equation in θ, given $\mu(x,y)$ and $\psi(x,y)$. Given its solution, the electron current density vector $\bar{J}$ is then known, from (8) and (9).

The manner in which the current density scale factor J_o is determined is best deferred until after a discussion of the boundary conditions which must be satisfied by the solutions of these basic equations.

2.04 Boundary Conditions

We regard the left and right borders of the rectangular region dealt with by the model as symmetry planes such that ψ, θ, n, p, and J_y are even functions of x, while J_x is an odd function. Image theory then requires that these functions all be periodic in x, the periodicity being twice the channel

length $X_{channel}$ of Figure 1(b). A consequence of this implied periodicity is that the source and drain islands shown dotted in Figure 1(a) are "squeezed out of the picture," being replaced by infinitesimally thin source and drain "contacts" which serve as sources or sinks for current and electric flux lines. The assignment of boundary conditions on ψ and n to these "contacts" bears careful scrutiny.

2.04.1 Boundary Conditions on ψ and n--We select the charge-neutral source island as the zero reference for electric potential, $\psi = 0$ (even though that region has been "squeezed out of the picture" in the model), and assume that the contact potentials of all metal-semiconductor and metal-oxide contacts are identical and, therefore, can be ignored.* The p-substrate, in the absence of any external bias voltages, assumes the normalized "built-in" potential:

$$\psi_{EQ} = -\ell n(N_D N_A) \ , \qquad (14)$$

which is also assumed by the gate. If the substrate and gate are then biased positively** with respect to the source at potentials V_{SUB} and V_G, respectively, the boundary conditions stipulated along the two horizontal borders in Figure 3(a) are obtained.

Consider next the source and drain "contacts" which, as stated above, are assumed to coincide with the metallurgical junction planes. Letting U be the normalized potential with zero reference redefined (for the present discussion) to be that of the charge-neutral p-region, Kennedy [6] shows rigorously that the potential U_J resulting in the plane of the metallurgical junction defining an abrupt p-n junction is:

---

*Differences in contact potential of the gate and substrate contacts and of the oxide-silicon interface can be modeled by assigning appropriate numerical values to the surface charge term Q_{SS}, for which our model does account.

**Later is this development, we tacitly assume that V_{SUB} will always be a negative numeric.

[6] D.P. Kennedy, IEEE Trans. Electron Devices, ED-22, 988 (1975).

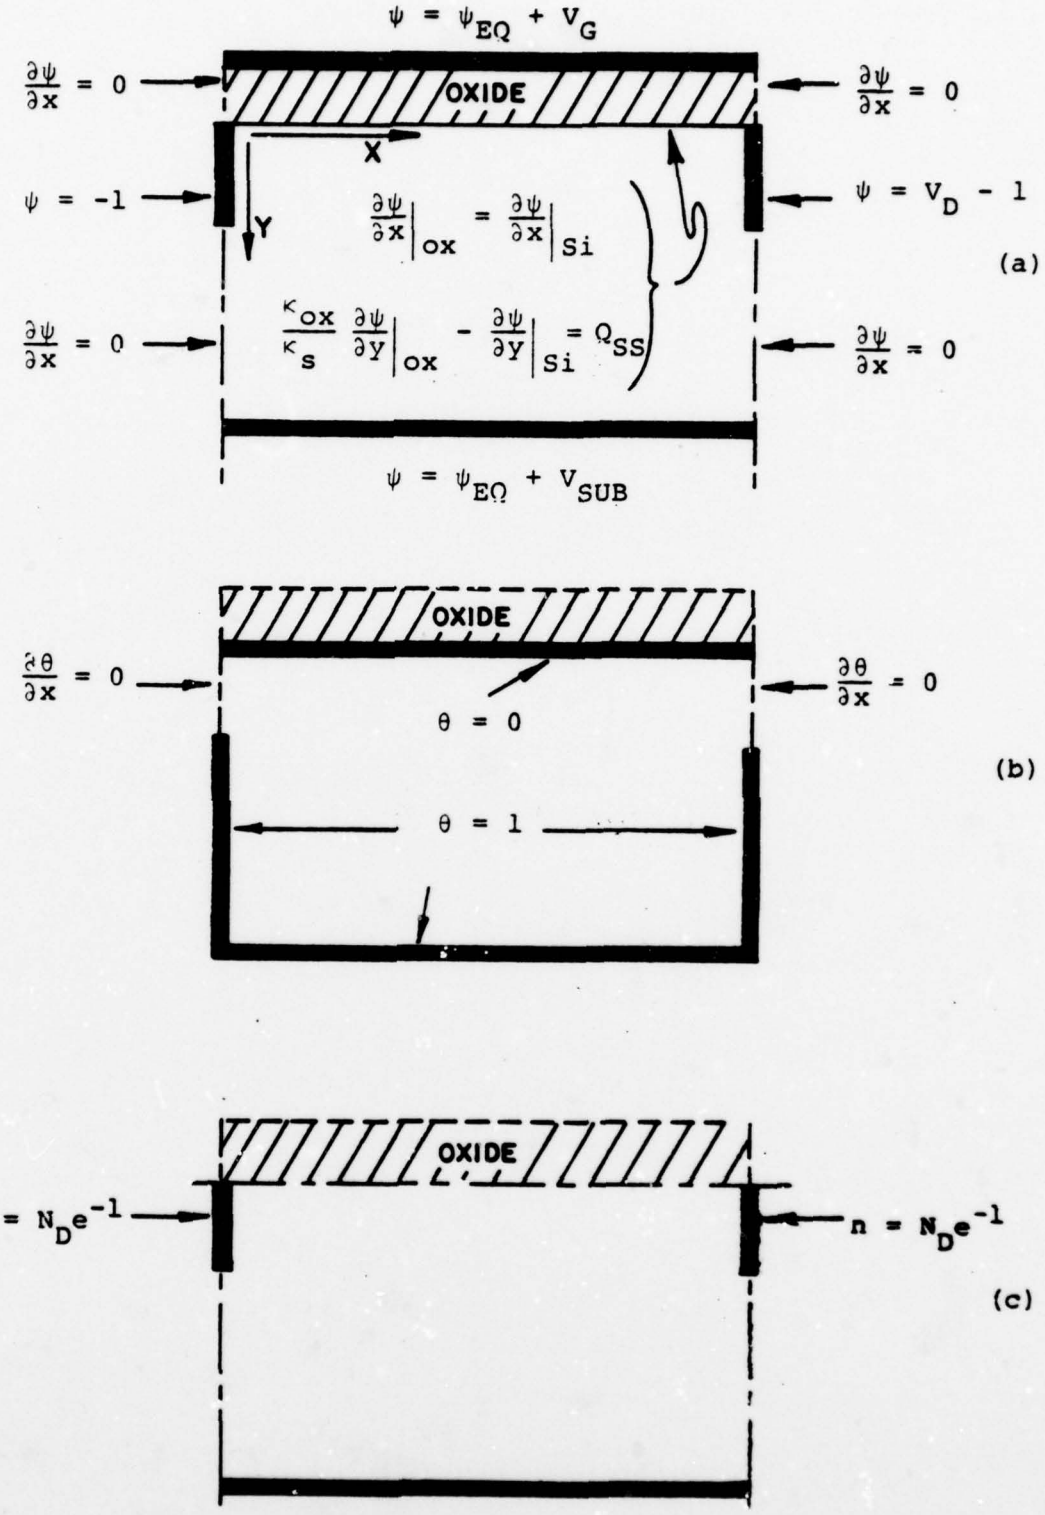

Figure 3 Boundary conditions for: (a) $\psi(x,y)$, (b) $\theta(x,y)$, and (c) $n(x,y)$.

$$U_J = U_T\left[\frac{N_D}{N_A+N_D}\right] + \left[\frac{N_A-N_D}{N_A+N_D}\right]\left[1 - \exp(-U_T)\right], \qquad (15)$$

where U_T is the total potential appearing across the p-n junction:

$$U_T = \ell n(N_D N_A) + U_{applied} . \qquad (16)$$

(Note that positive $U_{applied}$ in (16) results in a reverse-biased junction, consistent with Kennedy's convention.)

Consider some typical numerical values in (15) and (16). With $n_i' = 1.5\text{x}10^{10}$ cm^{-3}, $N_D' = 10^{19}$ cm^{-3}, $N_A' = 10^{16}$ cm^{-3} (the primes flag unnormalized constants), $\ell n(N_D N_A)$ assumes the numerical value 33.7, and the exponential term in (15) is entirely negligible except for negative values of $U_{applied}$ (i.e., forward bias) approaching that numerical magnitude. Furthermore, since $N_D >> N_A$, (15) simplifies tremendously, becoming:

$$U_J \simeq U_T - 1 . \qquad (17)$$

Since the drain junction is always operated reverse-biased, with $V_D > 0$, (17) is valid at the drain "contact."

Consider the source "contact," which does become forward-biased due to band bending near the oxide-silicon interface as the applied gate potential V_G is made positive with respect to the source. At the onset of strong inversion, the total normalized potential drop across the n^+p source junction right at the oxide-silicon interface will be reduced to $U_T = \ell n(N_D/N_A)$, which assumes the value $U_T = 6.9$, using the same numerical values for N_D' and N_A' assumed above. Again, the exponential term in (15) is negligible. We conclude that (17) is still a valid approximation for the source contact, at least for N_D/N_A ratios of 10^3 or higher. The approximation begins to become questionable only when $N_D/N_A < 10^2$, but at the source "contact" only.

Reverting to our convention of selecting the charge-neutral source island for zero reference potential, we conclude from (17) that the appropriate boundary conditions on ψ at the source and drain "contacts" are $\psi = -1$, and $\psi = V_D - 1$, respectively, as shown in Figure 3(a).

The remaining boundary conditions on ψ shown in that figure assure the symmetry assumed at the left and right borders of the region, and assure proper matching of the solutions of (1) and (7) at the oxide-silicon interface. Note that the condition imposed upon the normal derivatives of ψ at that interface allows for the inclusion of surface charge Q_{SS}, a feature not included by Mock. (The condition stated in the figure for the normal derivatives assumes an unfamiliar form because of the normalized variables employed.)

The numerical method later to be described for determining the electron number density $n(x,y)$ requires that n be specified along the borders of the rectangular region only at the source and drain "contacts." The fact that those "contacts" have potentials one normalized unit lower than those of the corresponding charge-neutral source and drain islands (where $n = N_D$) leads to the boundary conditions on n depicted in Figure 3(c).

2.04.2 Boundary Conditions on θ--Referring to (8) and (9), we note that θ is defined only in terms of its spatial derivatives. This means that its magnitude can be arbitrarily bounded. A convenient choice for those bounds is $0 \leq \theta \leq 1$, with θ specified to be zero along the oxide-silicon interface as in Figure 3(b). Tacitly assuming that the substrate (back-gate) will always be biased negatively with respect to the source ($V_{SUB} \leq 0$), so that no back-gate current flows, the appropriate boundary conditions on θ along the remaining borders in the figure are those shown. The stipulation $\frac{\partial \theta}{\partial x} = 0$ along the source and drain "contacts" assures zero tangential current at those "contacts," and is consistent with the implied symmetry conditions discussed earlier.

Bounding θ between zero and unity has two useful consequences, both stemming from eq. (8): 1) the numerical value of θ at any point (x,y) is the decimal fraction of the total drain current which crosses the plane x through the layer bounded by the oxide-silicon interface and the plane y and, 2) the constant J_o appearing in (8) and (9) represents, physically, the total drain current per unit width of the inversion channel.

2.05 Determination of the Drain Current Factor J_o:

The drain current per unit width of channel, J_o, is obtained as follows. Eq. (11) gives:

$$\frac{\partial}{\partial x}\,(ne^{-\psi}) = \mu^{-1}e^{-\psi}J_o\,\frac{\partial\theta}{\partial y}\,. \qquad (18)$$

Integrating with respect to x along a horizontal line (y = constant) which intersects the source and drain "contacts," one obtains:

$$N_D\left[e^{-V_D} - 1\right] = J_o\int_0^{X_{channel}} \mu^{-1}e^{-\psi}\,\frac{\partial\theta}{\partial y}\,dx\,. \qquad (19)$$

Solving for J_o:

$$J_o = \frac{-N_D[1-e^{-V_D}]}{\int_0^{X_{channel}} \mu^{-1}e^{-\psi}\,\frac{\partial\theta}{\partial y}\,dx}\,. \qquad (20)$$

This is the same result used by Mock for calculating J_o, except for the factor N_D appearing in (20), which is absent in Mock's result ([1], eq. (10)). The reason for this difference is seated in the fact that Mock chose to set the electron quasi-Fermi Potential ϕ_n equal to zero in the charge-neutral source region, which makes $\psi = \ell n(N_D)$ in that region, whereas we have chosen to set $\psi = 0$ there. Note that the sign

of J_o changes if one were to perform the integration from $x = 0$ to the "image" drain contact at $x = -X_{channel}$. Thus, J_o is an odd function of x, as it must be in order to satisfy the symmetry conditions on J_x and J_y described in Section 2.04.

3.0 Finite-Difference Algorithms

Figure 4 defines the indices (I,J), and their bounds, used to identify each lattice point involved in implementing finite-difference algorithms for determining ψ, θ, and n. (The figure does not attempt to convey the graded nature of the lattice actually used.) As shown, two "interlaced" lattices are employed. The first, depicted by circles, represents the set of points at which the electrostatic potential ψ and the corresponding electron and hole densities n and p are numerically determined while the second, depicted by squares, represents the set of points at which the stream function θ is evaluated. This choice, although complicating the satisfaction of the boundary conditions on θ, allows the use of simple differencing between adjacent lattice points in evaluating $\partial\theta/\partial x$ and $\partial\theta/\partial y$.* Mock also employed such an interlaced pair of lattices.

Note that the oxide-silicon interface coincides with the upper border, J = JMAX, of the θ lattice. Although not shown in Figure 4, the ψ lattice extends vertically an additional four rows (uniformly spaced) beyond the row J = JMAX + 1 shown, to model the electrostatic potential

---

*In an earlier version of the model, the author chose to deal with a single lattice of points, rather than the interlaced lattices presently employed. In the development of the computer code for that choice, it was soon discovered that the nonuniform point spacings of the lattice precluded the use of simple differencing for evaluating derivatives. It was found necessary to fit parabolas through sets of three adjacent points in a row or column in order to evaluate the partial derivatives needed. While this was easily accomplished with a single subroutine for that purpose, nonetheless each such operation required 7 multiplications and 7 additions each time the subroutine was called. This imposed an unacceptable cost in computation time, and the approach was abandoned.

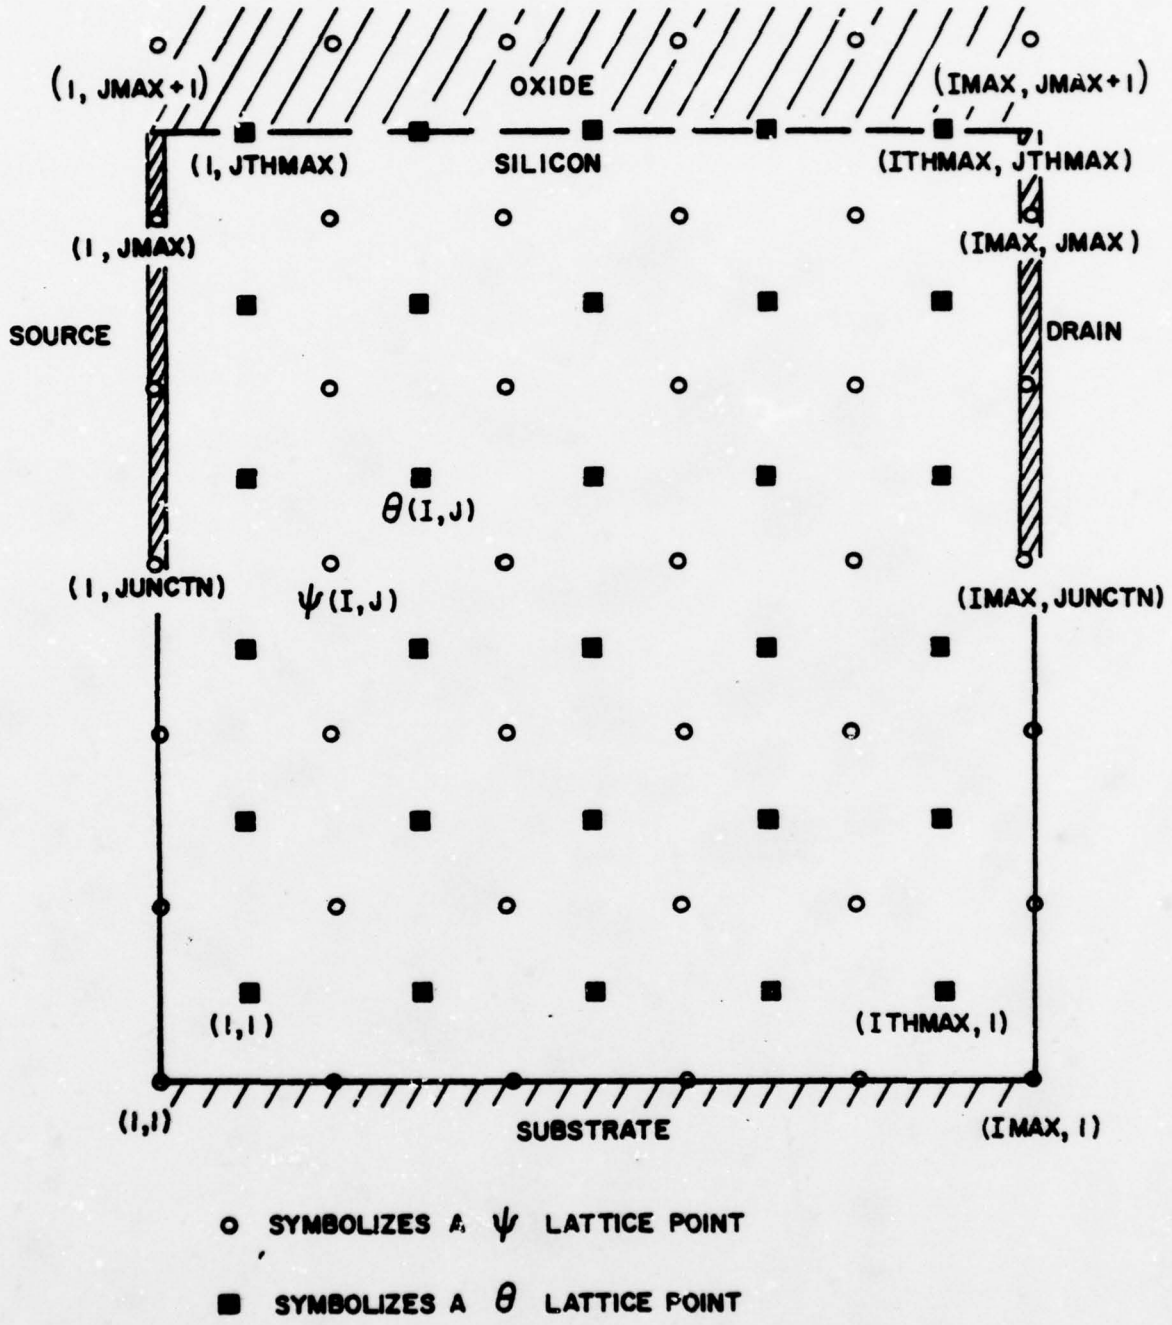

Figure 4 Layout of the interlaced ψ and θ lattices used in the finite-difference equations.

within the oxide region. Note, also, the convention adopted for the indices of the ψ lattice with respect to those of the θ lattice. (Given the ordered pair (I,J), the point of the θ lattice so identified is "northeast" of the corresponding point of the ψ lattice.)

3.01 Finite-Difference Algorithms for ψ

Consider the five point "star" of points in the ψ lattice shown in Figure 5. The dotted rectangle shown in that figure, having dimensions $\tilde{\Delta}x(I)$ by $\tilde{\Delta}y(J)$, is bounded at its four corners by the corresponding θ lattice points "NE, NW, SE and SW" of the central point P. (We shall adopt "points of the compass" notation, using subscripts in the difference equations to avoid repeated use of the index pairs (I,J), (I+1,J), etc., which are used in their FORTRAN counterparts in the computer program.) The lengths $\tilde{\Delta}x(I)$, $\tilde{\Delta}y(J)$, abbreviated $\tilde{\Delta x}_P$ and $\tilde{\Delta y}_P$ in the difference equations, are defined to be:

$$\left.\begin{aligned} \tilde{\Delta x}_P &= (\Delta x_E + \Delta x_W)/2 \ , \\ \tilde{\Delta y}_P &= (\Delta y_N + \Delta y_S)/2 \ . \end{aligned}\right\} \qquad (21)$$

This locates the θ lattice points always midway betweeen their neighboring ψ lattice points.

Applying Gauss's law to the rectangular region surrounding the point (I,J) in Figure 5, one obtains:

$$B_P\psi_S + D_P\psi_W + E_P\psi_P + F_P\psi_E + H_P\psi_N = Q_P \ , \qquad (22)$$

where:

$$\left.\begin{aligned} B_P &= \tilde{\Delta x}_P/\Delta y_S \ , \\ D_P &= \tilde{\Delta y}_P/\Delta x_W \ , \\ E_P &= -(B_P+D_P+F_P+H_P) \ , \\ F_P &= \tilde{\Delta y}_P/\Delta x_E \ , \\ H_P &= \tilde{\Delta x}_P/\Delta y_N \ , \\ Q_P &= \int\int_{BOX} (N_A+n-p)\,dxdy \ . \end{aligned}\right\} \qquad (23)$$

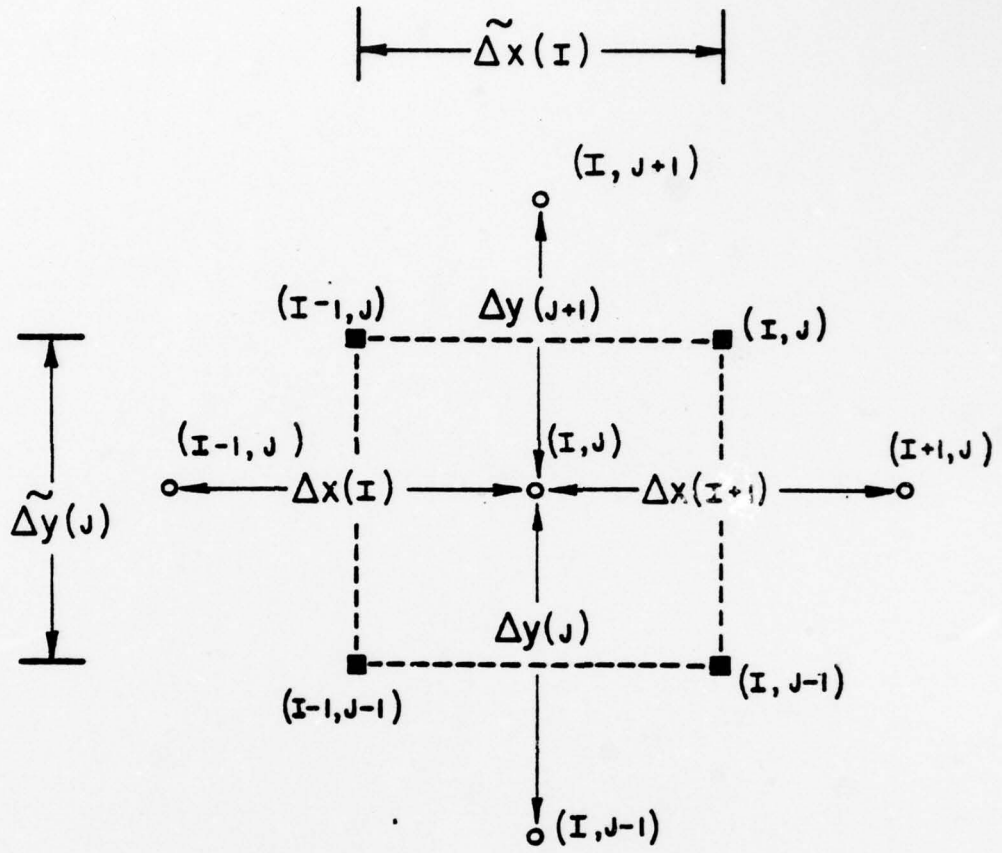

Figure 5 Five-point "star" of ψ-lattice points used in the finite-difference equation for ψ.

With a ψ lattice whose dimensions are I_{MAX} by (JMAX+5), the set of equations represented by (22) can be expressed in the matrix form:

$$[L] \cdot [\psi] = [Q] , \qquad (24)$$

where $[\psi]$ and $[Q]$ are rectangular matrices having the same dimensions as those of the ψ lattice, while [L] is a square matrix of dimensions (IMAX)*(JMAX+5) by (IMAX)*(JMAX+5). This matrix is sparse, having only five nonzero symmetrically positioned diagonal elements. Stone's iterative matrix factorization method [7] is employed in our model to solve (24) for the array ψ, given the array Q.

3.01.1 Implementation of the Boundary Conditions on ψ

The boundary conditions on ψ depicted in Figure 3(a) are enforced by appropriate modifications of the factors B_p, D_p, E_p, F_p, H_p, and Q_p in (22) at those ψ lattice points coinciding with the borders of the rectangular region modeled. These are next discussed.

3.01.1(a) Border Segments where ψ Is Specified--For ψ lattice points at which ψ is fixed, the coefficients B_p, D_p, F_p, and H_p are set to zero, while E_p is set to unity. Then the term Q_p in (22) is set equal to the known value of ψ at the point in question. In accordance with (22), this forces ψ_p to assume that known value at such border points.

3.01.1(b) Border Segments along Symmetry Planes--The boundary condition $\partial\psi/\partial x = 0$ is enforced at the symmetry planes in the following manner. At the left border, the coefficient D_p in (22) is set to zero, while F_p is doubled. The converse is applied at the right border. This assures the required symmetry of ψ at those border segments.

3.01.1(c) The Oxide-Silicon Interface--Since the ψ lattice has no points coinciding with the interface, the enforcement

---

[7] H.L. Stone, SIAM Jour. Numer. Anal., 5, 530 (1968).

of the proper boundary conditions on ψ there is somewhat more involved. We develop special forms of the finite-difference equation for ψ, which apply for the two rows of the ψ lattice, viz. J = JMAX and J = (JMAX+1), which bracket that interface. Figure 6 shows one set of points in those rows of the ψ lattice, and defines spacings $\Delta\eta_{ox}$ and $\Delta\eta_{si}$ which locate the interface. Through an appropriate choice of the ratio $(\Delta\eta_{ox}/\Delta\eta_{si})$, we develop an expression for the potential ψ_{surf} at the interface, in terms of the known potentials ψ_{ox} and ψ_{si} of the ψ lattice points north and south of it, such that the required discontinuity in $\partial\psi/\partial y$ is automatically satisfied. Then, an application of Gauss's law to the two rectangular regions shown crosshatched in the figure leads to the required special forms of the finite-difference equation in ψ for the two rows in question.

The boundary condition on $\partial\psi/dy$ at the interface is:

$$\left(\frac{\partial\psi}{\partial y}\right)_{si} = \left(\frac{\kappa_{ox}}{\kappa_{si}}\right)\left(\frac{\partial\psi}{\partial y}\right)_{ox} - Q_{SS} \ , \qquad (25)$$

which comes from applying Gauss's law to an inifinitesimally thin gaussian "pillbox" bracketing the interface, with the result expressed in terms of the normalized variables employed in our model. Here, κ_{ox} and κ_{si} are the relative permittivity of the oxide and silicon regions, respectively, while Q_{SS} is the surface charge density (if any) residing at the interface. In addition to this condition, we have:

$$\psi_{si} = \psi_{ox} + \left(\frac{\partial\psi}{\partial y}\right)_{ox} \Delta\eta_{ox} + \left(\frac{\partial\psi}{\partial y}\right)_{si} \Delta\eta_{si} \ , \qquad (26)$$

$$\left(\frac{\partial\psi}{\partial y}\right)_{ox} = \left[\frac{\psi_{surf} - \psi_{ox}}{\Delta\eta_{ox}}\right] \ , \qquad (27)$$

$$\left(\frac{\partial\psi}{\partial y}\right)_{si} = \left[\frac{\psi_{si} - \psi_{surf}}{\Delta\eta_{si}}\right] \ , \qquad (28)$$

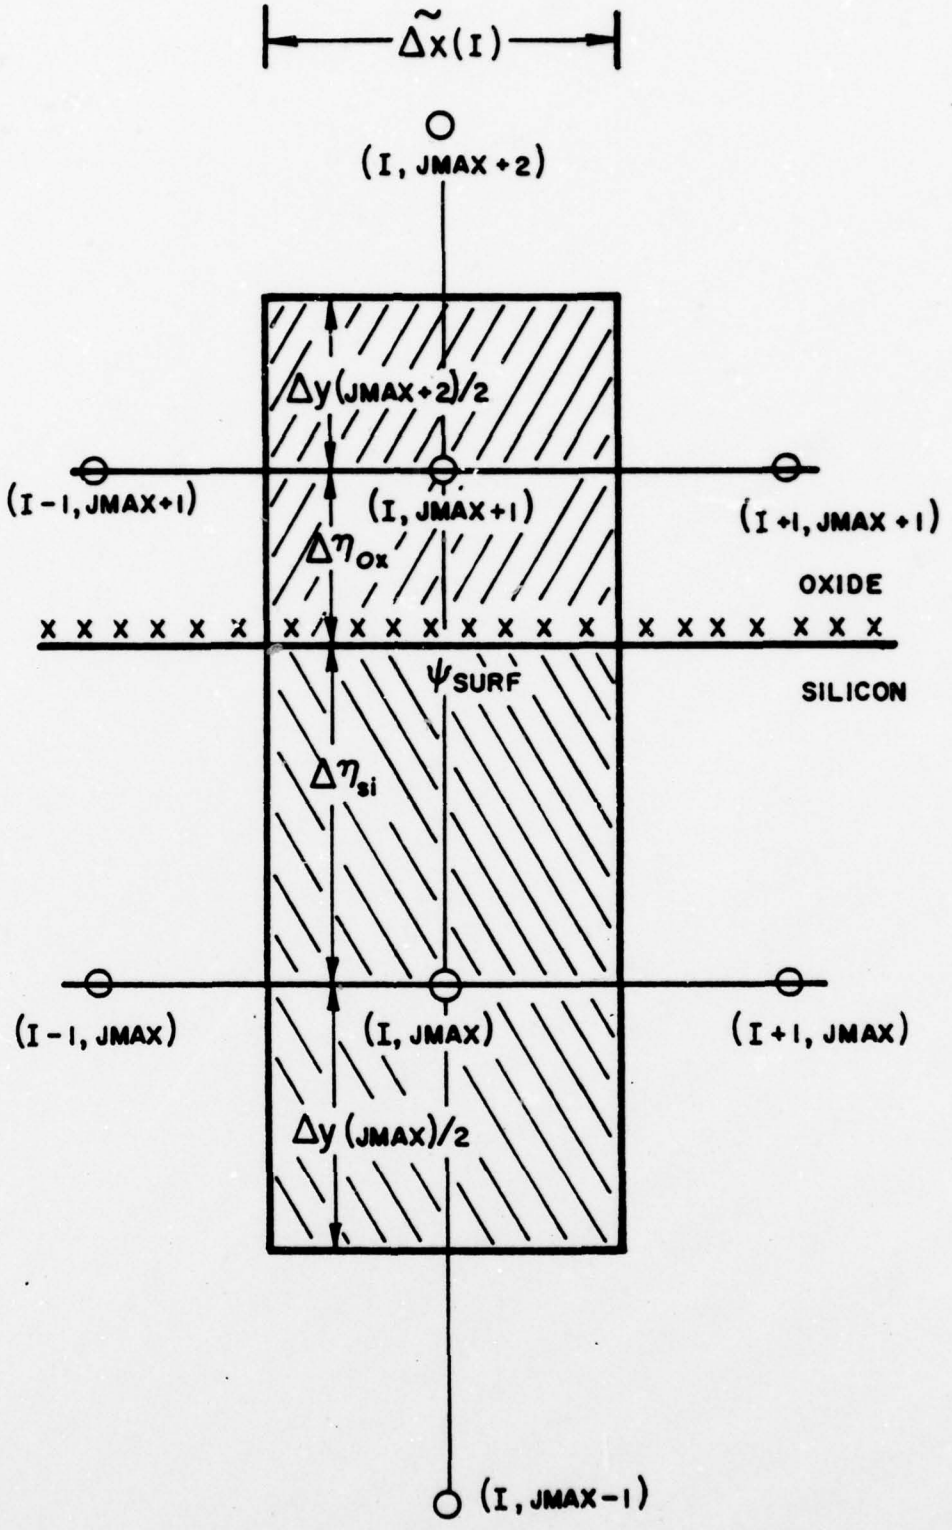

Figure 6 Boundary conditions on ψ at the oxide-silicon interface are enforced through an appropriate choice for the location of the interface, leading to special finite-difference equations applicable for the two ψ-lattice rows bracketing the interface.

with positive y defined to be vertically downward from the interface. These four equations relate five unknowns--$\Delta\eta_{ox}$, $\Delta\eta_{si}$, ψ_{surf}, $(\partial\psi/\partial y)_{ox}$, $(\partial\psi/\partial y)_{si}$--which means that the ratio $(\Delta\eta_{ox}/\Delta\eta_{si})$ can be specified at our convenience.

To find ψ_{surf} (and discover a convenient choice for $\Delta\eta_{ox}/\Delta\eta_{si}$), substitute (25) for $(\partial\psi/\partial y)_{si}$ and (27) for $(\partial\psi/\partial y)_{ox}$ into (26), obtaining:

$$\psi_{surf} = \left\{ \frac{\psi_{si} + \left(\frac{\kappa_{ox}}{\kappa_{si}}\right)\left(\frac{\Delta\eta_{si}}{\Delta\eta_{ox}}\right)\psi_{ox} + Q_{SS}\Delta\eta_{si}}{1 + \left(\frac{\kappa_{ox}}{\kappa_{si}}\right)\left(\frac{\Delta\eta_{si}}{\Delta\eta_{ox}}\right)} \right\} . \quad (29)$$

Choosing:

$$\Delta\eta_{ox} = \left(\frac{\kappa_{ox}}{\kappa_{si}}\right)\Delta\eta_{si} , \quad (30)$$

we obtain the simple relationship:

$$\psi_{surf} = \left[\frac{\psi_{ox} + \psi_{si}}{2}\right] + Q_{SS}\,\frac{\Delta\eta_{si}}{2} . \quad (31)$$

Furthermore, since $(\Delta\eta_{ox} + \Delta\eta_{si}) = \Delta y(JMAX+1)$, we find:

$$\Delta\eta_{si} = \Delta y(JMAX+1)/[1 + (\kappa_{ox}/\kappa_{si})] , \quad (32)$$

$$\Delta\eta_{ox} = \Delta y(JMAX+1)\left[\frac{(\kappa_{ox}/\kappa_{si})}{1 + (\kappa_{ox}/\kappa_{si})}\right] . \quad (33)$$

The result of the above procedure is that the potential at the interface, ψ_{surf}, is now known in terms of the potential at its north and south ψ lattice neighbors, with the simple relationship expressed by (31) resulting from locating the interface as prescribed by (32) and (33). These three equations assure that the boundary condition on $(\partial\psi/\partial y)$ at the interface is automatically satisfied, as is the boundary condition on $(\frac{\partial\psi}{\partial x})$.

Now apply Gauss's law to the rectangular region shown in Figure 6 which encompasses the ψ lattice point (I,JMAX) just below the interface. Again, adopting "points of the compass" notation, the electrostatic flux entering the upper surface of that rectangle is $-\tilde{\Delta}x_p(\psi_p-\psi_{surf})/\Delta\eta_{si}$. Using (31) to relate ψ_{surf} to ψ_N and ψ_p, the resulting finite-difference equation still assumes the form given by (22). However, the terms H_p and Q_p appearing in (23) (and only those) are now modified becoming:

$$\left.\begin{aligned} H_p &= \tilde{\Delta}x_p/2\Delta\eta_{si} \ , \\ Q_p &= \iint_{BOX} (N_A+n-p)\,dxdy - Q_{SS}\tilde{\Delta}x_p/2 \ , \end{aligned}\right\} \qquad (34)$$

which apply for any ψ lattice point in the row J = JMAX.

An identical procedure, applied to the rectangular region encompassing the point (I,JMAX+1) in Figure 6 shows the terms B_p and Q_p to be:

$$\left.\begin{aligned} B_p &= \tilde{\Delta}x_p/2\Delta\eta_{ox} \ , \\ Q_p &= -\left(\frac{\kappa_{si}}{\kappa_{ox}}\right)Q_{SS}\tilde{x}_p/2 \ , \end{aligned}\right\} \qquad (35)$$

which apply for any Ψ lattice point in the row J = JMAX+1.

As a check of these results, it is satisfying to find that if there <u>were</u> no interface (i.e., if $\kappa_{ox} \equiv \kappa_{si}$, and $Q_{SS} \equiv 0$), then (32) and (33) result in $\Delta\eta_{si} = \Delta\eta_{ox} = \Delta y(JMAX+1)/2$, so that both (34) and (35) reduce to the corresponding expressions for B_p, H_p, and Q_p given in (23), which apply for all rows of the ψ lattice except the two which bracket the oxide-silicon interface.

Mock did not use the above procedure for dealing with the interface. Instead, he defined a transformation of coordinate variable $y \rightarrow z$ in the oxide region, chosen so that $(\partial\psi/\partial z)_{ox} = (\partial\psi/\partial y)_{si}$ at the interface, even though

$(\partial\psi/\partial y)$ is discontinuous there. (This is equivalent to defining a modified oxide thickness.) While this approach possesses the advantage of requiring no special forms of the finite-difference equations at the interface, it precludes the inclusion of surface charge Q_{SS} in the model. Since we wish to include such, we choose not to follow Mock's approach, and implement the above described procedure instead.

3.01.2 Numerical Algorithm for the Charge Term Q_P

The charge term Q_P in (23) represents the net bulk charge enclosed by the rectangular region surrounding each ψ-lattice point, the corners of that region coinciding with the points of the θ-lattice NE, NW, SE, and SW of the point P. A simple approximation for Q_P is obtained from (23) to be:

$$Q_P \approx (N_A + n - p)\tilde{\Delta}x_P\tilde{\Delta}y_P \ , \qquad (36)$$

which assumes that n and p can be regarded as constant throughout the rectangular region.

While more elaborate approximations for Q_P are possible (e.g., a two-dimensional implementation of Simpson's rule) they involve more complex programming logic to handle lattice points adjacent to the four borders of the lattice, and are more costly in terms of computation time. Such more sophisticated procedures were tried by the author , but were found to be unnecessary, and were subsequently abandoned.

3.02 Finite-Difference Algorithm for the Stream Function θ

The partial differential equation in θ, eq. (13), is repeated here for convenience of reference:

$$\frac{\partial}{\partial x}\left(\mu^{-1}e^{-\psi}\,\frac{\partial\theta}{\partial x}\right) + \frac{\partial}{\partial y}\left(\mu^{-1}e^{-\psi}\,\frac{\partial\theta}{\partial y}\right) = 0 \ . \qquad (13)$$

Our present version of the computer model does not incorporate provisions for field-dependent electron mobility. Therefore, μ^{-1} can be factored from (13), and ignored. If the field dependence of μ is to be retained, as a refinement to be later incorporated, several subroutines in the computer program will require revision.

Figure 7 focuses upon a point (I,J) of the θ lattice, and its nearest neighbors. Simple differencing gives the partial derivatives of θ at the four points shown as crosses in the figure:

$$\left.\begin{aligned}
\left(\frac{\partial\theta}{\partial x}\right)_E &= \left[\frac{\theta_E - \theta_P}{\tilde{\Delta}x_E}\right] , \\
\left(\frac{\partial\theta}{\partial x}\right)_W &= \left[\frac{\theta_P - \theta_W}{\tilde{\Delta}x_W}\right] , \\
\left(\frac{\partial\theta}{\partial y}\right)_N &= \left[\frac{\theta_P - \theta_N}{\tilde{\Delta}y_N}\right] , \\
\left(\frac{\partial\theta}{\partial y}\right)_S &= \left[\frac{\theta_S - \theta_P}{\tilde{\Delta}y_S}\right] .
\end{aligned}\right\} \qquad (37)$$

The numerical value of $e^{-\psi}$ at each of those four points is determined in the manner next to be described.

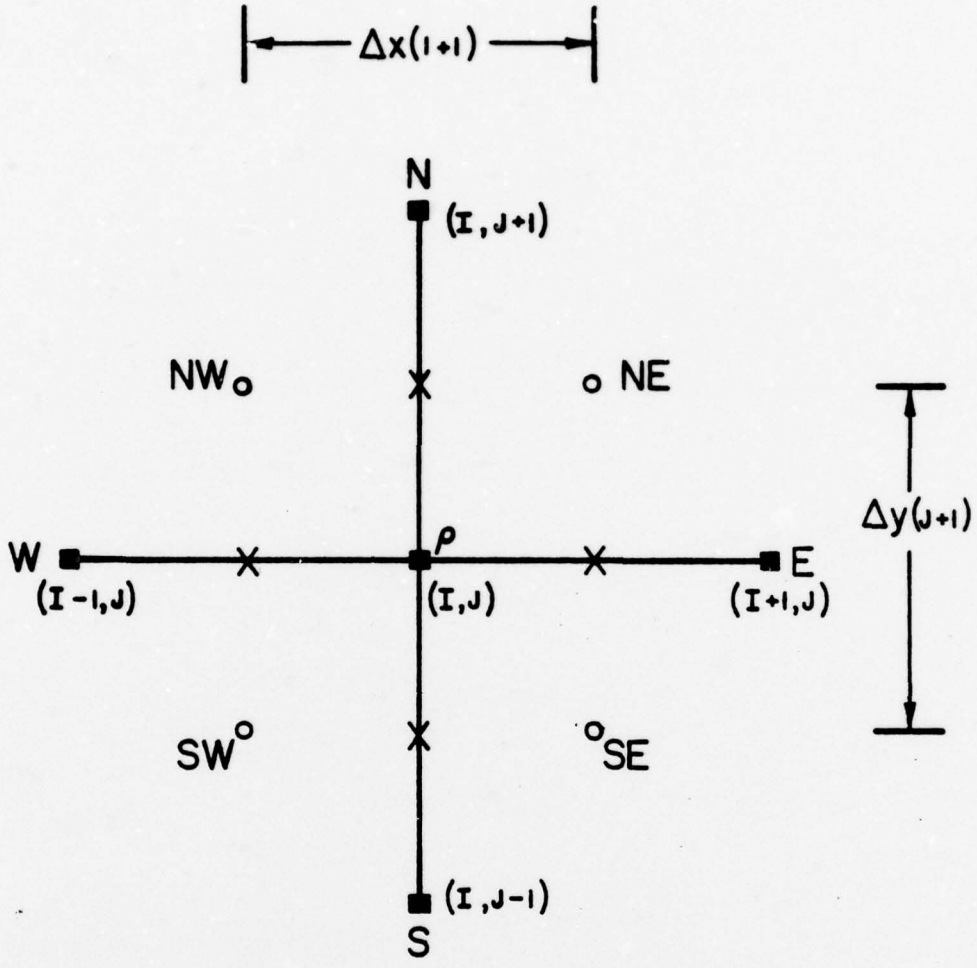

Figure 7 Five point "star" of θ-lattice points used in the finite-difference equation for θ.

Consider the four ψ lattice points located NE, SE, SW, and NW of the θ lattice point P. Assume a linear dependence of ψ along the borders of the rectangle defined by those four points, then evaluate an average value of $e^{-\psi}$ along each of those four borders, as did Mock [1], assigning the four averaged values to the respective points indicated by the crosses in the figure. (Mock describes this approach as a critical factor in achieving accuracy.) The result is:

$$\left.\begin{aligned} \langle e^{-\psi}\rangle_E &= \left[\frac{e^{-\psi_{NE}} - e^{-\psi_{SE}}}{\psi_{SE} - \psi_{NE}}\right], \\ \langle e^{-\psi}\rangle_W &= \left[\frac{e^{-\psi_{NW}} - e^{-\psi_{SW}}}{\psi_{SW} - \psi_{NW}}\right], \\ \langle e^{-\psi}\rangle_N &= \left[\frac{e^{-\psi_{NE}} - e^{-\psi_{NW}}}{\psi_{NW} - \psi_{NE}}\right], \\ \langle e^{-\psi}\rangle_S &= \left[\frac{e^{-\psi_{SE}} - e^{-\psi_{SW}}}{\psi_{SW} - \psi_{SE}}\right]. \end{aligned}\right\} \qquad (38)$$

With the $e^{-\psi}$ values thus determined at the four points midway between the N, E, S, and W points of the θ lattice, the finite-difference form of (13) becomes (assuming constant mobility μ):

$$\Delta y_P\left[\langle e^{-\psi}\rangle_E\left(\frac{\theta_E-\theta_P}{\tilde{\Delta}x_E}\right) - \langle e^{-\psi}\rangle_W\left(\frac{\theta_P-\theta_W}{\tilde{\Delta}x_W}\right)\right]$$

$$+ \Delta x_P\left|\langle e^{-\psi}\rangle_S\left(\frac{\theta_S-\theta_P}{\tilde{\Delta}y_S}\right) - \langle e^{-\psi}\rangle_N\left(\frac{\theta_P-\theta_N}{\tilde{\Delta}y_N}\right)\right| = 0, \qquad (39)$$

where Δx_P and Δy_P have been introduced as shorthand notation for $\Delta x(I+1)$, $\Delta y(J+1)$ in Figure 7. (See Figure 5 for the geometric definitions of the $\tilde{\Delta}x$ and $\tilde{\Delta}y$ factors in the above equation.)

As was the case with the finite-difference equation for ψ discussed earlier, the set of equations (39) can be represented in matrix form. The resulting sparse matrix contains only five nonzero symmetrically positioned diagonal elements. The matrix equation is solved for θ, given ψ, using the block-line iterative procedure described by Varga [8].

The finite-difference equation for θ expressed by (39) is deceptively simple. Its implementation produces nontrivial challenges because of the exponential dependence upon ψ evident in (38). To illustrate, consider a modest drain voltage of 10 volts. In our normalized variables, this translates to a numerical value on the order of 400. But the IBM 370/165 used in this development produces overflow and underflow with the operation $e^{\pm|x|}$ when $|x|$ exceeds approximately 175. Not only is this limit obviously violated in regions near the drain, in the example cited, but along the entire channel as well when the gate voltage exceeds about 4.5 volts.

The modus operandi developed for dealing with this problem is the following. One <u>never</u> deals with positive x values in the operation e^{x}. One <u>always</u> alters the equation being treated so that only negative exponents are encountered. Furthermore, one endeavors <u>always</u> to reformulate that equation so that x represents <u>differences</u> in the potential between adjacent ψ lattice points, rather than the magnitude of ψ itself. Finally, one always tests the magnitude of the negative exponent before attempting the operation of exponentiation, avoiding "underflow" messages by use of the approximation $e^{-x} \approx 0$ when x is found sufficiently large.

---

[8] R.S. Varga, Matrix Iterative Analysis, p. 194, Prentice-Hall, New York (1962).

To implement these restrictions, the average $e^{-\psi}$ functions in (38) are first reexpressed by factoring the exponential term whose exponent is least negative. This leaves within the brackets an exponential term whose negative exponent represents differences in ψ between adjacent lattice points. Following this, the four terms in (38) are again factored by the exponential term outside of the brackets whose exponent is least negative. Since the right hand side of (39) is zero, the latter factor can be cancelled from the equation. Again, this results in exponential terms whose negative exponents represent differences in ψ between adjacent lattice points. The subprogram which implements this procedure selects one of 16 possible cases in the process of determining which exponents are least negative.

3.02.1 Implementation of the Boundary Conditions on θ

The finite-difference equation in θ, equation (39), can be reexpressed to read:

$$B_P\theta_S + D_P\theta_W + E_P\theta_P + F_P\theta_E + H_P\theta_N = 0 \ , \qquad (40)$$

which then takes on the same form as the finite-difference equation in ψ, equation (22). As was the case with ψ, the boundary conditions on θ shown in Figure 3(b) are established by means of appropriate modifications in the coefficients B_P, D_P, E_P, F_P, and H_P in (40).

3.02.1(a) Border Segments where θ=1--The fact that the θ lattice interlaces the ψ lattice (Figure 4) means that the boundary condition θ=1 cannot strictly be enforced at the borders where that condition applies (Figure 3). However, those borders are remote from the region under the oxide-silicon interface where "the action" occurs, so this is not considered to be a serious drawback. What is done is to enforce θ=1 along the column (or row) of θ lattice points

imagined to be present just outside of the rectangular region modeled. Thus, for example, at the left border in Figure 4 the coefficient D_p is calculated in the usual manner. Then the right hand side of (40) is set equal to the negative of D_p and the term involving θ_W in (40) is omitted, which is equivalent to enforcing θ_W to be unity. Similar procedures are applied at the right border and along the lower border of the substrate.

3.02.1(b) Border Segments where $\partial\theta/\partial x = 0$--Again, we imagine two columns of the θ lattice just outside of the rectangular region modeled in Figure 4. At the left border, therefore, we wish to enforce $\theta_W = \theta_P$. This is achieved by calculating D_p and E_p in the usual manner, then summing them to obtain a revised value for E_p. The coefficient D_p in (40) is then set to zero. A similar procedure is applied at the right border.

3.02.1(c) The Oxide-Silicon Interface where $\theta=0$--Here, the row J = JTHMAX of the θ lattice coincides with the interface. The condition $\theta=0$ is enforced along that row by setting B_p, D_p, F_p, and H_p to zero, while setting E_p to unity in (40).

3.03 Finite-Difference Algorithm for the Drain Current Factor J_o

The row of the ψ lattice just below the oxide-silicon interface is selected for the line integral contained in (20), to evaluate the drain current factor J_o. The trapezoidal rule is applied to evaluate the integral. Simple differencing of θ on the interlaced θ lattice provides $\partial\theta/\partial y$ at the centroid of each interval Δx. The value of $e^{-\psi}$ at that centroid is again specified to be an average obtained by assuming a linear variation of ψ between adjacent ψ lattice points along the row:

$$\langle e^{-\psi} \rangle = \left[\frac{e^{-\psi_E} - e^{-\psi_W}}{\psi_W - \psi_E} \right] . \qquad (41)$$

As in the case of evaluating θ discussed earlier, special procedures are employed to avoid overflow and underflow due to machine limitations.

3.04 Finite-Difference Algorithm for the Electron Number Density n

Equation (10) when separated into its x and y components, gives:

$$\frac{\partial}{\partial x}\left(ne^{-\psi}\right) = \frac{J_x}{\mu} e^{-\psi} , \tag{42}$$

$$\frac{\partial}{\partial y}\left(ne^{-\psi}\right) = \frac{J_y}{\mu} e^{-\psi} . \tag{43}$$

Expressing (42) in finite-difference form:

$$\left[\frac{n(I+1,J)e^{-\psi(I+1,J)} - n(I,J)e^{-\psi(I,J)}}{\Delta x(I+1)}\right] = \frac{J_x}{\mu} \langle e^{-\psi(I,J)} \rangle . \tag{44}$$

(Here we resort to the use of the indices (I,J) identifying ψ lattice points because the "points of the compass" notation employed earlier becomes awkward.) Note that an average value for $e^{-\psi}$ is assigned to the point midway between the points I+1 and I of the row J. That is:

$$\langle e^{-\psi(I,J)} \rangle = \left[\frac{e^{-\psi(I+1,J)} - e^{-\psi(I,J)}}{\psi(I,J) - \psi(I+1,J)}\right] . \tag{45}$$

Equations (44) and (45), when combined, can be reexpressed so as to involve only differences in ψ:

$$n(I+1,J) = n(I,J)e^{-[\psi(I,J)-\psi(I+1,J)]} + \frac{J_x}{\mu}\left[\frac{1 - e^{-[\psi(I,J)-\psi(I+1,J)]}}{\psi(I,J) - \psi(I+1,J)}\right] \Delta x(I+1) . \tag{46}$$

Alternatively:

$$n(I,J) = n(I+1,J)e^{-[\psi(I+1,J)-\psi(I,J)]} - \frac{J_x}{\mu}\left[\frac{1 - e^{-[\psi(I+1,J)-\psi(I,J)]}}{\psi(I+1,J) - \psi(I,J)}\right]\Delta x(I+1) \quad . \qquad (47)$$

Equations (46) and (47), together with the vertical counterpart of (46) derived in the same manner from (43), form the basis for the finite-difference algorithm for the electron density n, which proceeds as follows. Consider any row J $\geq$ JUNCTN (see Figure 4) which intersects the vertical source and drain "contacts" at the left and right borders where n is known. Starting at the left border, (46) is applied recursively to "march" along that row, toward the right border, until a potential minimum is encountered. When this occurs, then one switches to the right border and applies (47), recursively, to "march" to the left toward the last point at which n was previously calculated. In this manner, the electron member density is filled in row by row, for all rows of the ψ lattice which intersect the source and drain "contacts." Note that the exponentials encountered with this procedure always involve negative exponents.

The next step in the procedure then utilizes the vertical counterpart of (46), derived from (43). In this case, one starts at the row J = JUNCTN, where n is now known, and "marches" vertically downward to the substrate contact, column by column. Again, only negative exponents are encountered in any exponentiation operations required.

To avoid underflow, appropriate approximations are invoked in the subprogram which implements this procedure when the negative exponents encountered become sufficiently large. Similarly, appropriate approximations are applied when the denominators in (46) and (47), and the vertical counterpart of (46) approach zero, to avoid divide checks.

The "marching" algorithm described above is precisely the one suggested by Mock [1], who states that the procedure of switching directions at the point where ψ passes through a minimum suppresses the buildup of roundoff errors. In spite of this assertion, one intuitively feels uneasy about any numerical method which only makes use of information about the solution at one border without "pumping into" the solution some information about the boundary condition at the other border as well. The "marching" method fails to do so, and blithely assumes that, where the two solutions meet, continuity in n will not be violated.

The author felt sufficiently uneasy about this to try a different approach. Combining pairs of equations of the form of (46) by summing them, so as to couple the points I-1, I, and I+1 in a common row J, a tridiagonal matrix results from the set of equations relating n along that row. Given J_x and ψ as knowns, Gaussian elimination is then implemented to obtain n along such a row. This approach achieves the goal of "pumping into" the equations simultaneous information about the boundary conditions at both ends of the row in question. Interestingly, the two methods are found to give identical results (within the three significant figures printed out) in regions where the electron density is numerically important, i.e., in the inversion layer. Both approaches produce <u>negative</u> electron densities in regions where the numerical magnitude of n is negligible in comparison with the acceptor density N_A. (These nonphysical negative densities are believed due to roundoff errors.) Insofar as these negative densities are concerned, the "marching" method is found superior. With it, they occur with values of n an order of magnitude lower than observed with the more sophisticated tridiagonal matrix approach.

4.0 The Iterative Procedure

The basic equations defined in Section 2, and their finite-difference counterparts developed in Section 3, constitute a set of coupled, nonlinear equations for which a self-consistent solution is obtained by means of an iterative procedure. The one followed is basically the same as that adopted by Mock [1], with one important modification which will be clarified in Section 4.03.

The iterative procedure starts with initial "guesses" for $\psi(x,y)$, $\theta(x,y)$, $n(x,y)$ and $p(x,y)$ which will be discussed in Section 4.04. It then proceeds as follows. Given n and p, the charge Q_P associated with each ψ lattice point P is then known (Subsection 3.01.2). Equation (22) is then solved, using Stone's method, to provide a new estimate for ψ. A new estimate for θ is then generated, followed by new estimates for n and p consistent with the new ψ and θ distributions. The procedure is then repeated until convergence is achieved, as determined by convergence criteria specified as input data by the user. Two differing procedures--PICARD iteration, and GUMMEL's algorithm--are employed in the implementation of this iterative sequence. These will next be discussed.

4.01 Picard Iteration

The Picard iteration procedure utilizes only "past history" to predict the next iterate for ψ, and is employed to achieve "coarse" convergence. Consider the m^{th} iteration step to have just been completed, so that $\psi^{(m)}$, $\theta^{(m)}$, $n^{(m)}$, and $p^{(m)}$ have been determined. (Values for step (m-1) are also available, as needed, except when m=0, which corresponds to the initial "guess.") Given these, (22) is solved, yielding a new solution for the potential distribution, which we designate $v^{(m+1)}$. With it, the improved approximation $\psi^{(m+1)}$ for the correct potential $\psi(x,y)$ is obtained from:

$$\psi^{(m+1)} = \psi^{(m)} + \alpha_m[v^{(m+1)}-\psi^{(m)}] + \beta_m[\psi^{(m)}-\psi^{(m-1)}] \ , \qquad (48)$$

where α_m and β_m are underrelaxation parameters, adjusted for each iteration step m in the manner to be described next. With $\psi^{(m+1)}$ thus specified, the corresponding new estimates for $\theta^{(m+1)}$, $n^{(m+1)}$ are then determined.

As was done by Mock [1], we adopt the Chebyscheff sequence of relaxation parameters α_m and β_m discussed by Forsythe and Wasow [9] for estimating appropriate values of those parameters at each iteration step m and, as did Mock, we reinitiate the sequence whenever the new residual $|v^{(m+1)}-\psi^{(m)}|_{max}$ turns out to be greater than the residual found in step m. (Mock interprets this as an indicator that the nonlinearity of the problem is becoming evident.) This sequence of relaxation parameters is given by, [9]:

$$\alpha_m = \frac{4\cosh(m\omega)}{(b-a)\cosh([m+1]\omega)} , \tag{49}$$

$$\beta_m = \frac{\cosh([m-1]\omega)}{\cosh([m+1]\omega)} , \tag{50}$$

where

$$\omega = \cosh^{-1}\left[\frac{b+a}{b-a}\right] . \tag{51}$$

The parameters b and a in (51) are the upper and lower bounds, respectively, of the eigenvalues of the matrix equation (24). The initial values of this Chebyscheff sequence, as prescribed by Forsythe and Wasow, are determined by,

$$\alpha_o = 2/(b+a) , \tag{52}$$

$$\beta_o = 0 . \tag{53}$$

The implementation of this procedure requires an estimate for the upper and lower bounds b and a of the eigenvalues of the matrix equation (24). The

---

[9] G.E. Forsythe and W.R. Wasow, Finite-Difference Equations for Partial Differential Equations, pp. 226-235. Wiley, New York (1960).

estimate for a is not critical, but that of b is. Too small an estimate for b leads to failure of the relaxation procedure to converge, while too large an estimate leads to extremely slow convergence. We have adopted the estimate for b suggested by Mock ([1], eq. (21))*:

$$b = \frac{Y_{sub}}{4X_{channel}} \iint (n+p)\,dxdy \ , \qquad (54)$$

the double integral being evaluated over the entire rectangular substrate region by application of the trapezoidal rule in two dimensions. The parameter b is evaluated using initial estimates for n and p to be described below.**

Mock [1] points out that since large values of b lead to slow rates of convergence, and since its magnitude is proportional to the total number of free carriers in the substrate region, a savings in computation time can be achieved by applying the Picard iteration process, initially, with a reduced donor density assigned to the source and drain, until coarse convergence criteria are satisfied. Having achieved this, he then assigns the correct donor density to those regions and switches to Gummel's iterative algorithm for the remainder of the computation, with tightened convergence criteria applied.

---

*Mock's eq. (21) contains a factor ε_s which is missing in (54). This is because of differences in Mock's choice of normalized variables and the choice which we have adopted.

**At one time, the program included steps to reevaluate the parameter b each time the Chebyscheff sequence was reinitiated, on the basis that the estimates for n and p at that stage of the computation should be better than the estimates previously employed for that purpose. Computer experiments later showed that not only is this unnecessary but also that it usually caused the number of iterations required for convergence to increase, rather than decrease.

4.02 Gummel's Algorithm

Unlike the Picard iteration method just described, which uses only "past history," Gummel's algorithm [10] incorporates a new prediction for p and n at each iterative step. Because this prediction is based upon a linear approximation of the exponential functions appearing in the Boltzmann relations for those densities, it is efficient in terms of computation speed only when the estimates of ψ, p, and n are close to the "correct" values when it is initiated.

Let $\psi^{(m)}$, $n^{(m)}$ and $p^{(m)}$ be the values obtained at iteration step m. Let $\psi^{(m+1)} = \psi^{(m)} + \delta^{(m+1)}$, and assume that $\delta^{(m+1)} << \psi^{(m)}$. Then:

$$e^{\psi^{(m+1)}} \approx e^{\psi^{(m)}} [1+\delta^{(m+1)}] . \qquad (55)$$

Applying this approximation to (2) and (3), one has

$$n^{(m+1)} \approx n^{(m)} [1 + \delta^{(m+1)}] , \qquad (56)$$

$$p^{(m+1)} \approx p^{(m)} [1 - \delta^{(m+1)}] , \qquad (57)$$

which assumes that the electron quasi-Fermi potential ϕ_n does not change appreciably between iteration steps (m) and (m+1). Assuming these conditions to be met, Poisson's equation, (1), gives for $\psi^{(m+1)}$:

$$\nabla^2\psi^{(m+1)} - [n^{(m)}+p^{(m)}]\psi^{(m+1)} = [N_A+n^{(m)}-p^{(m)}] - [n^{(m)}+p^{(m)}]\psi^{(m)} , \qquad (58)$$

which is Gummel's algorithm.

The finite-difference equivalent of (58) can be cast into the same form as (22). Only the coefficient E_p in (23)

[10] H.K. Gummel, IEEE Trans. Electron Devices ED-11, 455 (1964).

is modified due to additional term $[n^{(m)} + p^{(m)}]\psi^{(m+1)}$ appearing on the left side of (58). Similarly, the charge term Q_p in (23) is modified due to the corresponding additional term on the right side of (58). The resulting matrix equation, corresponding to (24), is solved for $[\psi^{(m+1}]$, given $[Q^{(m)}]$, using Stone's iterative procedure.

4.03 A Modification of Mock's Iterative Procedure

As described above, Mock uses both the Picard iteration and Gummel's algorithm, the former being used to achieve coarse convergence at reduced donor density, the latter being used to achieve final tightened convergence at full donor density. Initially, the author adopted this same procedure. However, computational experiments with our computer model have revealed that this procedure does not seem to be necessary. The author has found that not only is it possible to apply Gummel's algorithm directly at the outset, with full donor density, but also that the rate of convergence can be substantially enhanced if one applies overrelaxation in so doing. This approach proceeds as follows.

Let $\psi^{(m)}$ be the potential corresponding to the m^{th} iterative step and let $v^{(m+1)}$ be the result of applying Gummel's algorithm at the $(m+1)^{th}$ iterative step. Then the new potential $\psi^{(m+1)}$ is obtained as:

$$\psi^{(m+1)} = \psi^{(m)} + \Omega(v^{(m+1)}-\psi^{(m)}) \quad , \qquad (59)$$

where Ω is an empirically determined relaxation parameter having a numerical value greater than unity.

That this procedure can result in a substantial reduction in computation time is illustrated in Figure 8, which plots the number of iterations required to achieve tight convergence ($\max|\psi^{(m+1}-\psi^{(m)}| \leq .02$) versus gate voltage, with drain voltage fixed, for a particular device. In this

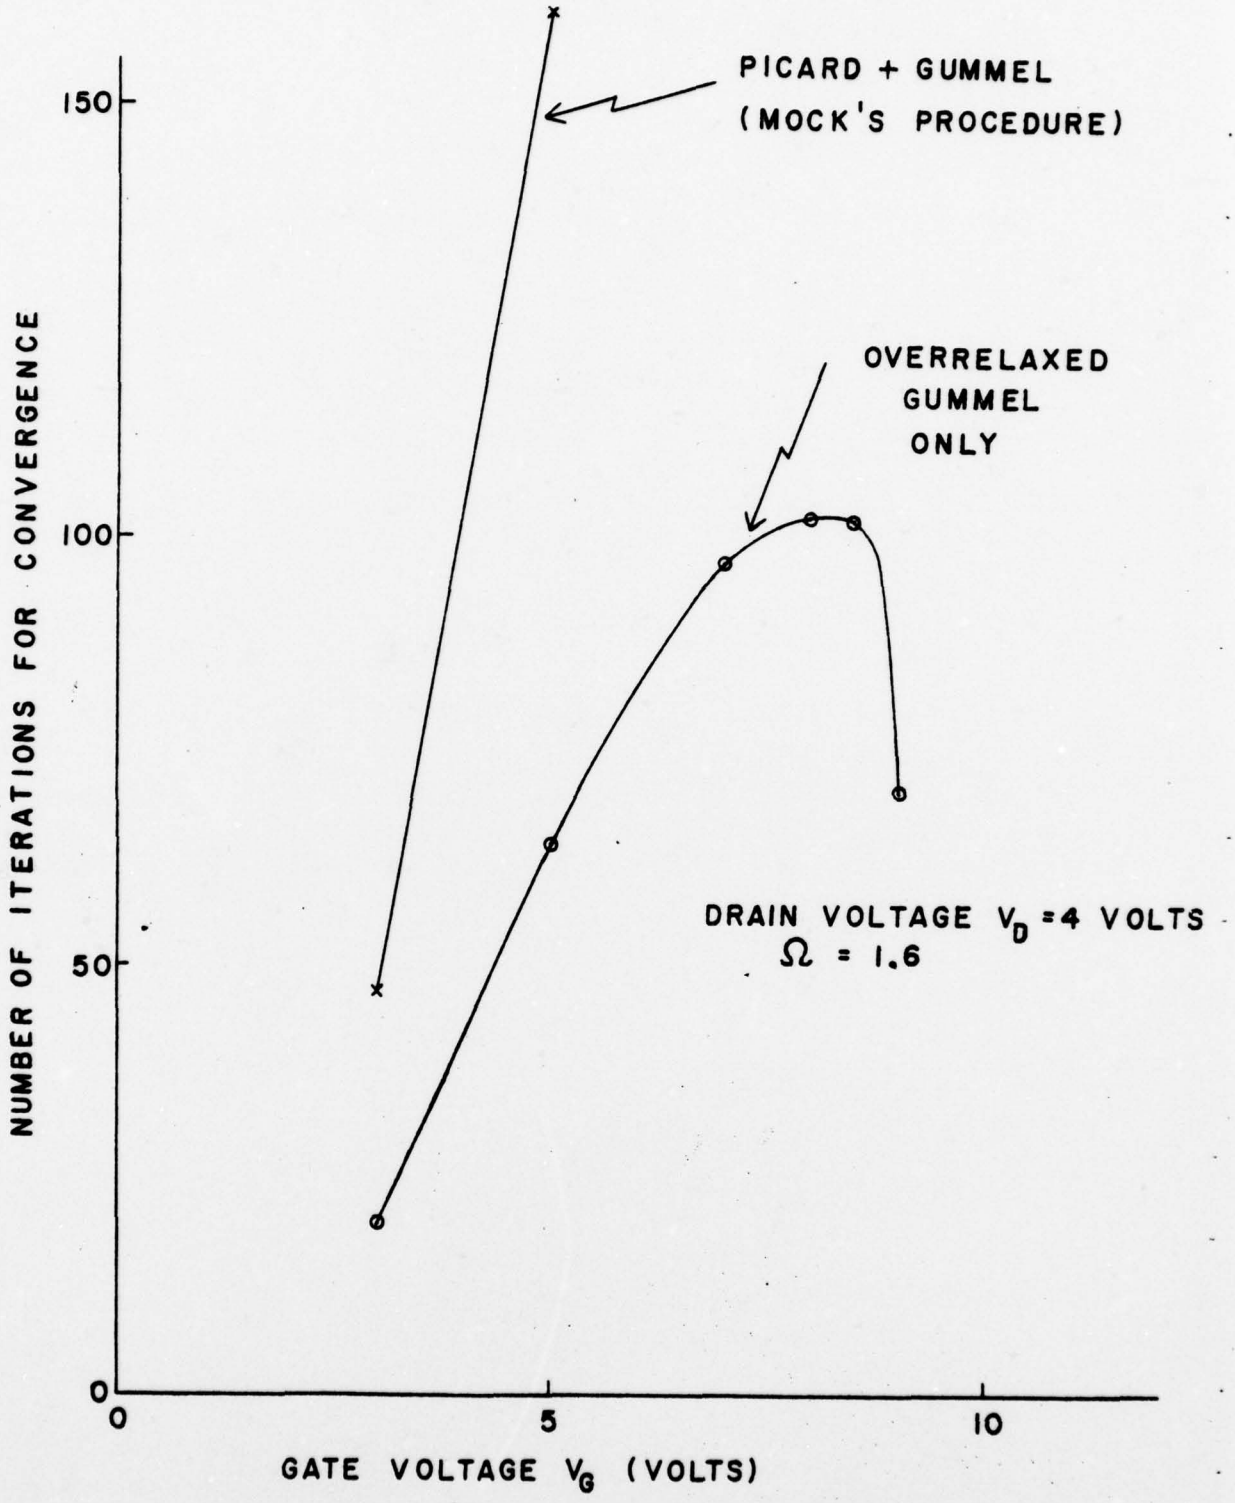

Figure 8 Number of iterations required for convergence of ψ to within .02 kT/q versus the gate voltage V_G, comparing Mock's iterative procedure with the overrelaxed Gummel procedure.

case, Ω was set to be 1.6, in the overrelaxation of Gummel's algorithm. In this experiment, four of the six points (V_G = 3,5,7,9) shown for the curve labeled "OVER-RELAXED GUMMEL ONLY" were generated in a single computer run requiring 190 seconds of CPU time (the remaining two points were generated in separate runs to fill in further detail). On the other hand, at V_G = 7 volts, the combined "PICARD + GUMMEL" procedure failed to converge at all within a 6-minute cut-off time that was specified for that particular run!

Figure 8 reveals that the number of iterations required for convergence is strongly dependent upon the degree of charge inversion in the conducting channel. Computational experiments have also shown that the effectiveness of over-relaxation is much more dramatic in the strong inversion case. This is illustrated in Figure 9, which plots the number of iterations required to achieve convergence with the overrelaxed Gummel procedure versus the overrelaxation parameter Ω. (The threshold voltage for this particular device is $\approx$2.5 volts.) The numerical values shown along the two curves give CPU time, in seconds, required with the Amdahl 470 V/6-II computer used for these experiments, and include compilation time in each instance.

The discovery that the Gummel algorithm alone can be used, and particularly the fact that overrelaxation can be applied with marked success with that algorithm, was made only during the final phases of this project. Consequently, the computer model has been revised so as to allow the user the flexibility of specifying the implementation of either Mock's iterative procedure, or the overrelaxed Gummel procedure alone, by means of a "flag" incorporated as part of the input data specified by him. Similarly, the value of the overrelaxation parameter Ω to be used is at the user's disposal, inasmuch as time did not permit an investigation of possible methods for automatically determining an optimum value (or possibly a sequence of values) for this parameter.

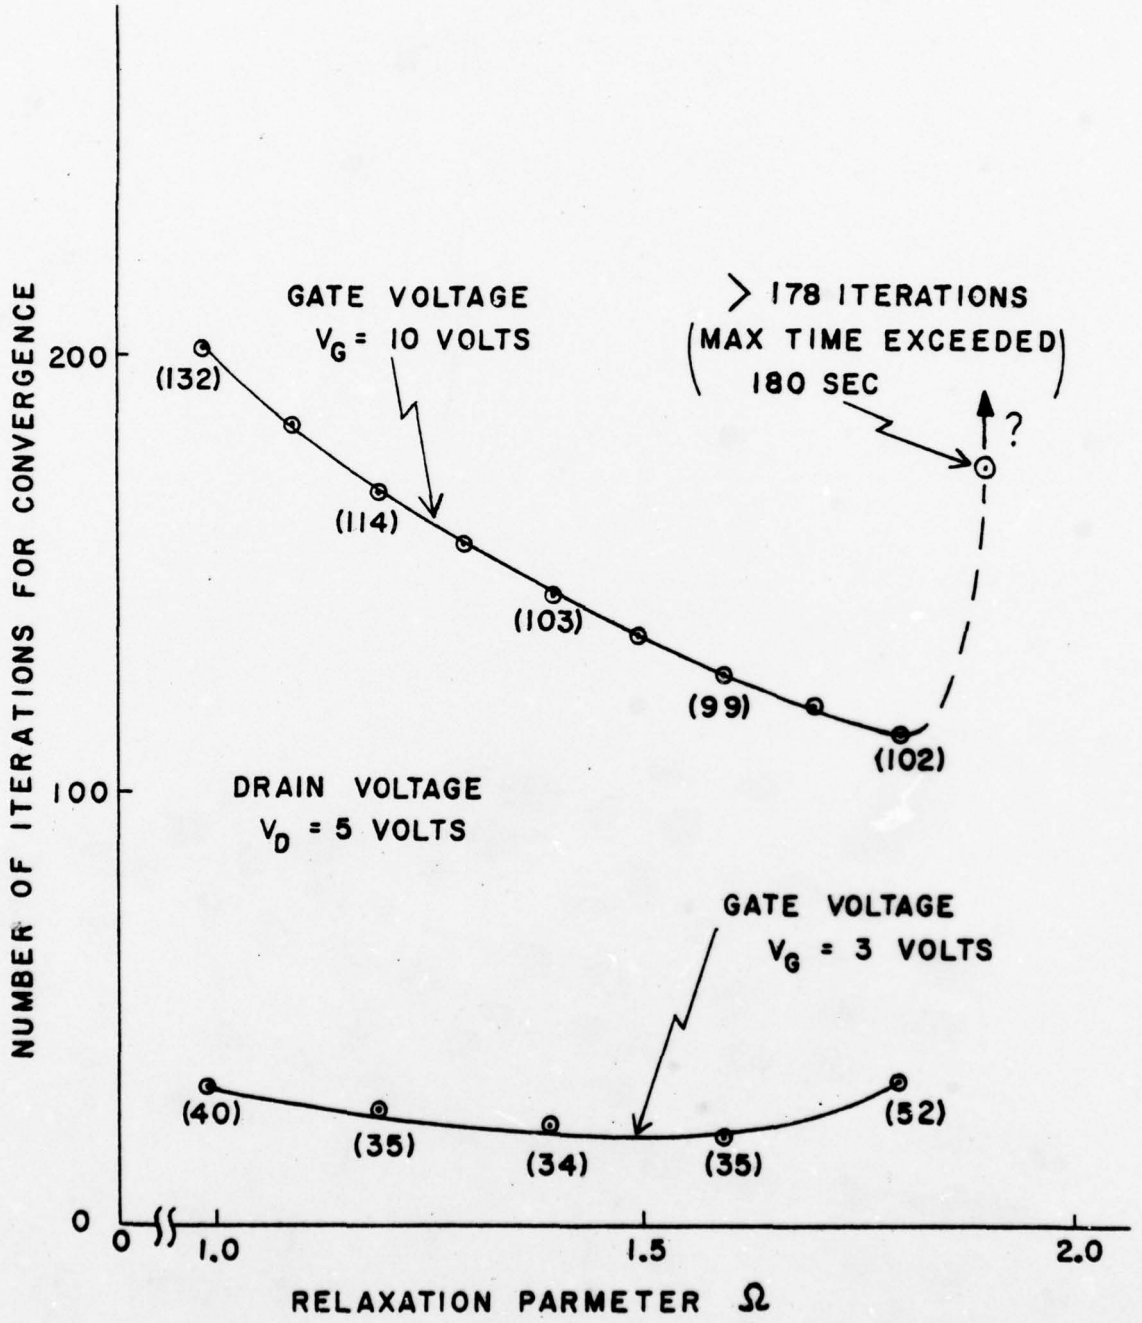

Figure 9 Number of iterations required for convergence of ψ to within .02 kT/q versus the overrelaxation parameter Ω used with Gummel's algorithm. The numerical values show CPU time, in seconds, required with an Amdahl 470 V/6-II computer.

4.04 Initial Estimates for $\psi(x,y)$, $\theta(x,y)$, $n(x,y)$, and $p(x,y)$

The initial estimates for ψ, θ, n, and p have been found to be a crucial factor in determining the number of iterations required to achieve convergence to a self-consistent solution. Early versions of our computer model were found to require from two to three times the number of iterations that were required with the IBM program developed by Mock. Much effort has been expended, in developing our model, to improve upon this early experience. These efforts have proven successful. Particularly, when only the Gummel algorithm is utilized, as described above, our model now requires from two to three times less iterations than does the IBM program, in most cases. This is attributed to the adequacy of the algorithms finally adopted for supplying the initial estimates. These will next be described.

4.04.1 Initial Estimate for $\psi(x,y)$

Figure 10(a) shows a sketch of the equipotential contours obtained from a two-dimensional, self-consistent solution of equations (1) through (7) for an MOSFET with a channel length of 5μm, operating in strong inversion in the saturation mode. The cross-hatched regions shown in the figure identify regions in which $\psi(x,y)$ can be regarded as essentially having one-dimensional dependence, $\psi(x,y) \approx \psi(x)$, where $\psi(x)$ is found, to good approximation, to exhibit the parabolic dependence on x predicted by the widely used depletion approximation of abrupt p-n junction theory. This parabolic dependence in the vicinity of the source and drain "contacts" is sketched in Figure 10(b) as the two dashed curves shown.

The dotted region in Figure 10(a) identifies the charge-neutral region of the substrate, where $\psi = \psi_{eq} + V_{SUB}$, and where $\nabla\psi=0$. The two depletion parabolas of Figure 10(b) merge

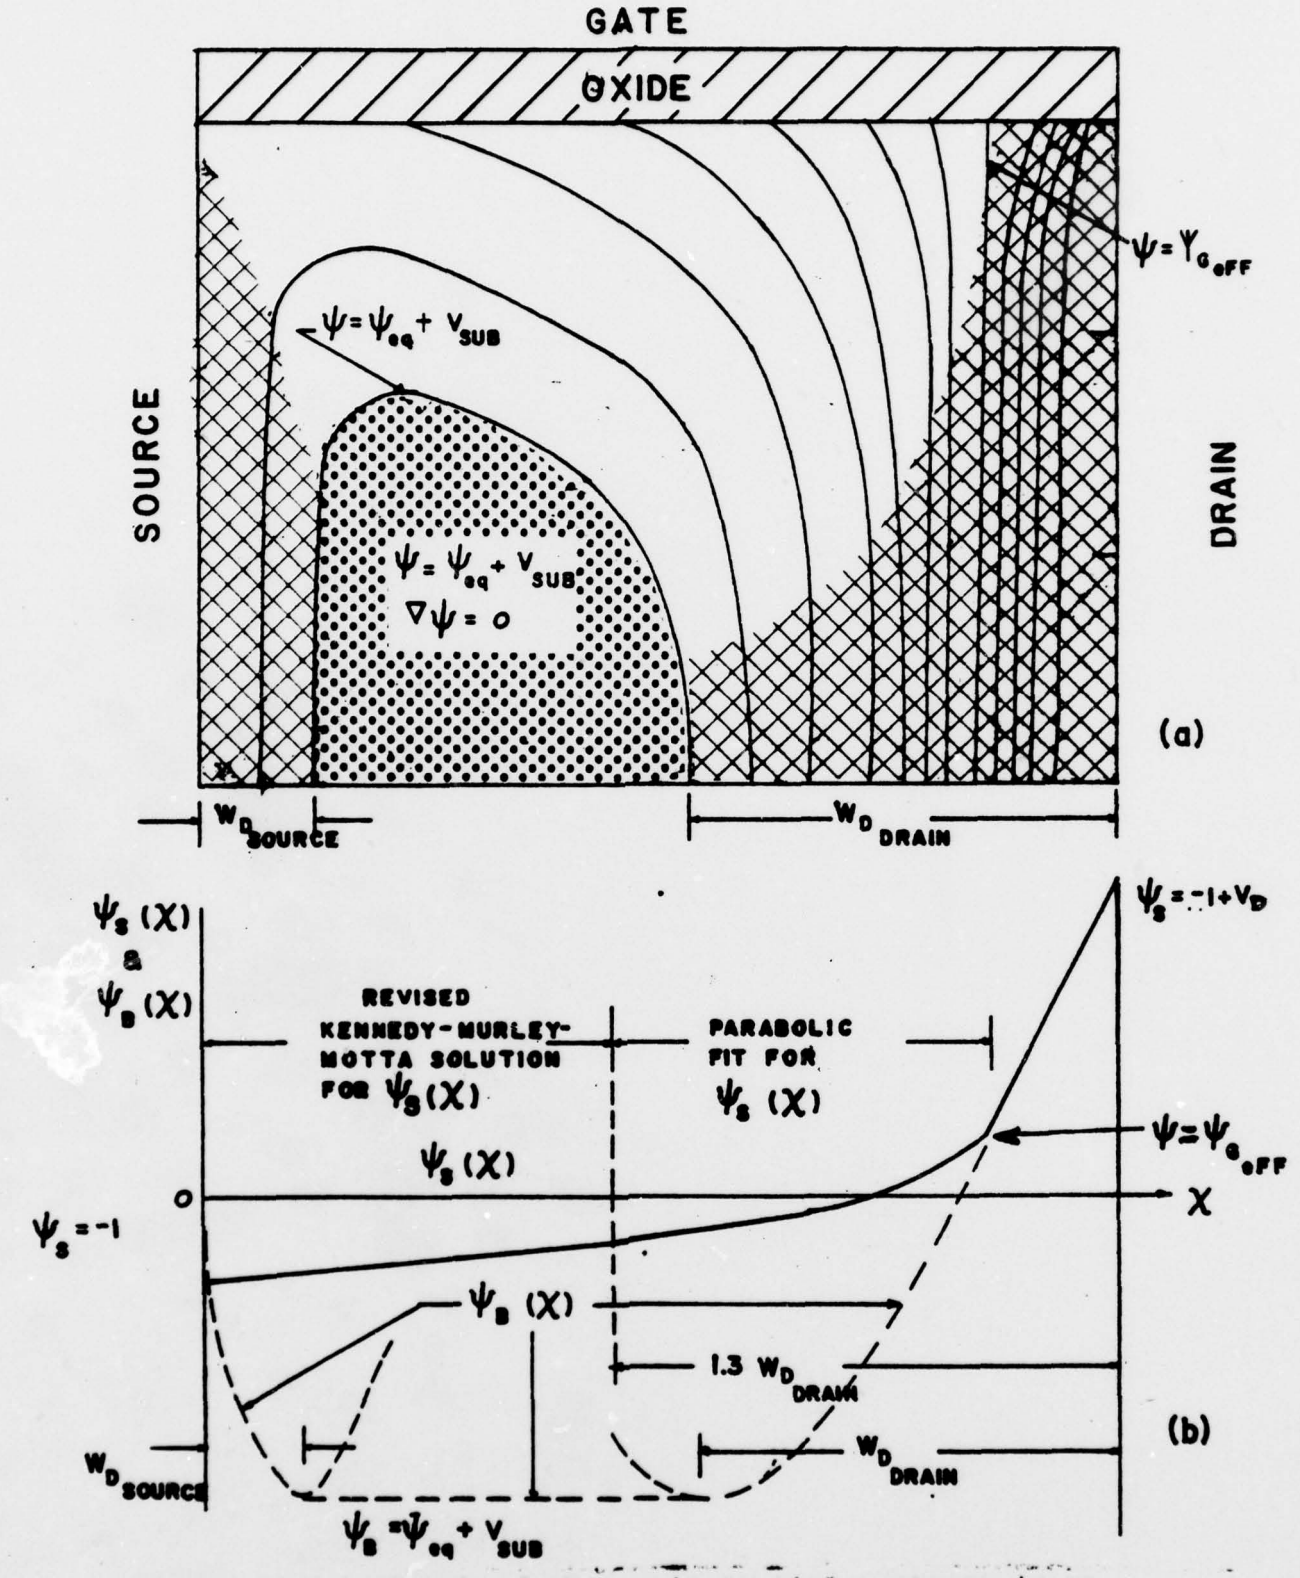

Figure 10 (a) Sketch of the equipotential contours in an MOSFET operating in saturation, providing insight into how to supply an initial estimate for $\psi(x,y)$. (b) Sketch of the potential $\psi_s(x)$ along the oxide-silicon interface, and $\psi_B(x)$ deep within the bulk material.

smoothly into the constant potential existent in that charge-neutral region. The composite dashed curve in Figure 10(b), for these three regions, serves to define the bulk potential $\psi_B(x)$, which is applicable deep within the substrate region, provided that $y < y_{JUNCTION}$ (see Figure 1(b)).

In contrast with the above regions, the unshaded region in Figure 10(a) depicts the region where $\psi(x,y)$ must be regarded as a two-dimensional function of the position coordinates x and y. At the oxide-silicon interface, y=0, it is effectively bounded on the left by the source itself, and on the right by the equipotential contour $\psi = \psi_{G_{eff}}$, which defines the point along the interface at which the component of electric field, E_y, normal to the interface vanishes. (In terms of the energy band diagrams commonly employed in MOSFET theory, this is the point along the channel at which the flatband condition occurs.) That contour is labelled in Figure 10(a) as $\psi = \psi_{G_{eff}}$, where:

$$\psi_{G_{eff}} = \psi_G + (k_{si}/k_{ox})y_{ox}Q_{ss} \quad , \tag{59}$$

with $\psi_G = \psi_{EQ} + V_G$, as defined in Figure 3(a). Equation (59) defines the surface potential at the interface ψ_s which leads to vertical electric field reversal. This condition occurs, of course, only in the saturation mode, when the drain potential ψ_D exceeds $\psi_{G_{eff}}$.

The approach that we have adopted for estimating the two-dimensional potential distribution $\psi(x,y)$ in the unshaded region of Figure 10(a) is the following. An estimate for the surface potential $\psi_s(x)$ is first obtained by using the one-dimensional theory for MOSFET operation developed by Kennedy and Murley [11], as modified by Motta [12]. In principle,

---

[11] D.P. Kennedy and P.C. Murley, IBM Jour. Res. & Dev., 17, 1 (1973).

[12] R.F. Motta, Steady State Theory for the Metal-Oxide-Semiconductor Field Effect Transistor, Ph.D. Dissertation, University of Florida, 1976.

this solution is applicable up to the value of x at which $\psi_s(x) = \psi_{G_{eff}}$. It has been found empirically, however, that it is better to terminate the Kennedy-Murley-Motta solution for $\psi_s(x)$ at a value of x about 1.3 times the drain depletion width, $W_{D_{drain}}$, from the drain itself, and to extend $\psi_s(x)$ parabolically beyond that point of termination. Said parabolic extension is then matched in magnitude and slope to the Kennedy-Murley-Motta solution at that point, defining two of the three constants required to describe a parabola. The third constant depends upon whether or not the flatband condition is reached at some x between the point at which the parabolic fit is applied and the location of the drain, itself. If $\psi_D < \psi_{G_{eff}}$, the parabolic extension of $\psi_s(x)$ is forced to equal the drain potential ψ_D at $x = x_{channel}$ (see Figure 1). Otherwise, $\psi_s(x)$ is forced to equal $\psi_{G_{eff}}$ at the value of x at which the parabolic drain depletion potential equals $\psi_{G_{eff}}$. The latter case is the one illustrated in Figure 10(b).

Given an estimate for $\psi_s(x)$ and $\psi_B(x)$, as determined in the manner described above, one-dimensional solutions of Poisson's equation (with y the geometric variable) are then obtained along each plane x corresponding to an index I of the ψ lattice. These one-dimensional solutions are forced to: (a) match $\psi = \psi_B(x)$, with zero slope $d\psi/dy$ in the shaded regions of Figure 10(a), and (b) match the "known" solution $\psi = \psi_s(x)$ at the oxide-silicon interface. Furthermore, these one-dimensional solutions are forced to satisfy the boundary condition on $d\psi/dy$ at the oxide-silicon interface by adjusting the electron quasi-Fermi potential ϕ_n so that eq. (25) is satisfied. (The latter function is assumed to be independent of y over the range of y covered by these one-dimensional solutions--an approximation.)

In the above manner, "reasonable" quasi-two-dimensional first estimates for $\psi(x,y)$ are established throughout the silicon substrate. The estimate for $\psi(x,y)$ in the oxide region assumes a linear dependence on y which matches the

"known" surface potential $\psi_s(x)$ at the interface and the gate potential ψ_G at the gate electrode.

4.04.2 Initial Estimate for $\theta(x,y)$

The initial estimate of the stream function $\theta(x,y)$ is based upon the observation that θ takes on the value of unity at about the point at which the electron number density becomes intrinsic (i.e., n=1), throughout most of the substrate region. Furthermore, θ is found to be essentially a function only of the coordinate x, except in regions immediately adjacent to the source and drain "contacts." This being the case, the one-dimensional solution for $\psi(y)$, utilized as described above in the unshaded region of Figure 10(a), is then used at the vertical plane corresponding with the edge of the source depletion region to estimate the location y_1 at which n=1. A parabolic estimate for $\theta(y)$ is then established which takes on the value of unity, with zero slope, at $y=y_1$, and which takes on the value of zero at the oxide-silicon interface, y=0. That parabolic estimate for θ is then assigned along all vertical planes corresponding to the index I of the θ lattice, thereby establishing a one-dimensional initial estimate for θ.

4.04.3 Initial Estimates for $n(x,y)$ and $p(x,y)$

Given initial estimates for $\psi(x,y)$ and $\theta(x,y)$, the corresponding initial estimate for the electron density $n(x,y)$ is obtained using the "marching" method described in Section 3.04. The hole density $p(x,y)$ is obtained by applying the Boltzmann relationship, eq. (3), since the hole quasi-Fermi potential ϕ_p is assumed invariable (eq. (5)), and takes on the value which causes p to equal N_A in the charge-neutral substrate region.

CHAPTER II

Evaluation of the Computer Model's Performance

In this chapter, we show comparisons of the results obtained from our computer model with those obtained for identical cases from the IBM program devised by Mock. We also show comparisons of the predictions obtained from our model with experimental data obtained for a particular MOSFET structure whose processing parameters have been characterized from test sites fabricated as an integral part of its chip.

1.0 Comparisons with Mock's Program

Figures 11 through 34 show comparisons of the results obtained from our model with those obtained from the program developed for IBM by Mock. The figures are ordered in groups of three: (1) $\psi(x)$ versus x along the oxide-silicon interface, (2) $\psi(y)$ versus y along the vertical plane perpendicular to the interface midway between the source and the drain, and (3) n(y) versus y along the same vertical plane. The eight cases represented by these data represent extremes of operation as follows:

1) Short channel (3μm) ($N_D = 10^{19}$ cm^{-3}, $N_A = 2\text{x}10^{16}$ cm^{-3}):
   - (a) Weak inversion, triode mode
   - (b) Weak inversion, saturation mode
   - (c) Strong inversion, triode mode
   - (d) Strong inversion, saturation mode

2) Long channel (10μm) ($N_D = 10^{19}$ cm^{-3}, $N_A = 2\text{x}10^{15}$ cm^{-3}):
   - (a) Weak inversion, triode mode
   - (b) Weak inversion, saturation mode
   - (c) Strong inversion, triode mode
   - (d) Strong inversion, saturation mode

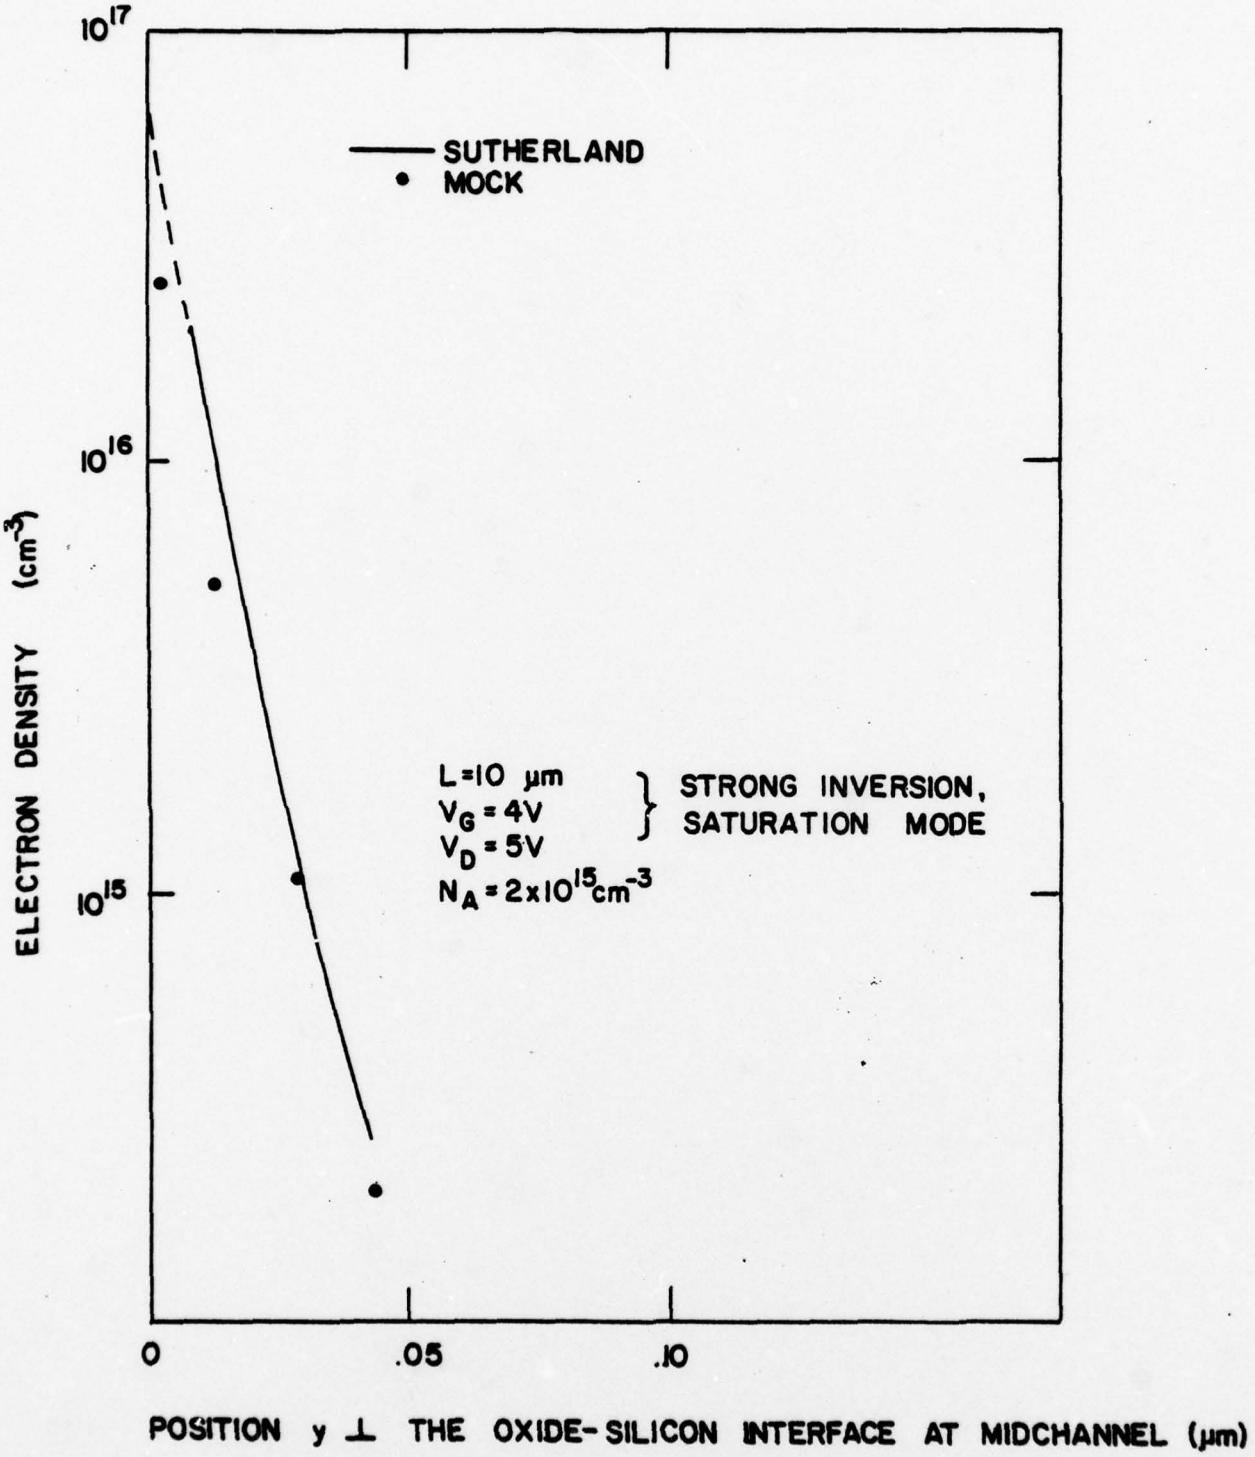

Figure 34 Comparison of the electron number density n(y) along the plane midway between source and drain, generated by this model and by Mock's model.

Table II compares the drain currents calculated by our model with those calculated by Mock's program for these eight cases

TABLE II -- COMPARISON OF DRAIN CURRENT CALCULATIONS
(ma/cm of channel width)

	Case	Our Model	Mock
L=3μm	Weak inversion, triode	.00164	.00127
	Weak inversion, saturation	.00184	.00148
	Strong inversion, triode	11.4	11.2
	Strong inversion, saturation	12.9	12.95
L=10μm	Weak inversion, triode	.000180	.000163
	Weak inversion, saturation	.000193	.000180
	Strong inversion, triode	23.4	22.9
	Strong inversion, saturation	27.8	29.0

It is seen that, in very weak inversion, the drain currents predicted by our model are only in fair agreement with those predicted by Mock's program, but in strong inversion the agreement is quite satisfactory. Insofar as the comparison of solution details is concerned, Figures 11 through 34 show essentially excellent agreement.

2.0 Comparison with Experiment

The experimental data with which we next compare our model were supplied to the author by Dr. D.L. Fraser, Jr. from measurements taken in conjunction with his Ph.D. dissertation [13], using the PMOS reliability test chips supplied

[13] D.L. Fraser, Jr., "Modeling and Optimization of MOSFET LSI Circuits," Ph.D. Dissertation, University of Florida, 1977. (This work was supported by the National Science Foundation, NSF Grant ENG-75-23078.)

by the National Security Agency, together with data on five additional test chips taken by NSA. The numerous test site configurations available on those chips, in addition to a silicon gate PMOS structure enabled Fraser to characterize the MOS device and its parameters in some detail. Full details are given in [13]. In particular such parameters as the device channel length and widch, the oxide thickness, the substrate doping, the source and drain doping, the gate threshold voltage V_T, and the flatband voltage V_{FB} are all deduced from such measurements. From these data, we deduced the effective mobility of holes in the inversion channel, (182 cm^2/volt-sec) as well. Thus, this appeared to the author to be an ideal structure for comparing the theoretical predictions of our model with experimental reality.

To utilize our model, which is for n-channel structures, to model the p-channel device, only two steps are necessary: (1) replace the electron mobility with the hole mobility, and (2) reverse the sign of Q_{ss}, since a positive Q_{ss} raises the threshold for a p-channel device, while lowering it for an n-channel device. Hence, to raise the threshold with an n-channel model, negative Q_{ss} should be used. We used an "effective" Q_{ss} ($Q_{ss_{eff}} = C_{ox} V_{FB}$), with V_{FB} the flatband voltage deduced from Fraser's measurements.

Figures 35 and 36 show comparisons of the drain current predicted with our model with Fraser's measurements. Figure 35 is for a fixed gate voltage putting the device into strong inversion (V_{GS} = 10V, with V_T = 2.18V). Figure 36 gives drain current versus V_{GS}, with the drain connected to the gate, so that $V_{DS} = V_{GS}$, and includes the weak inversion case as well. The results obtained are quite gratifying.

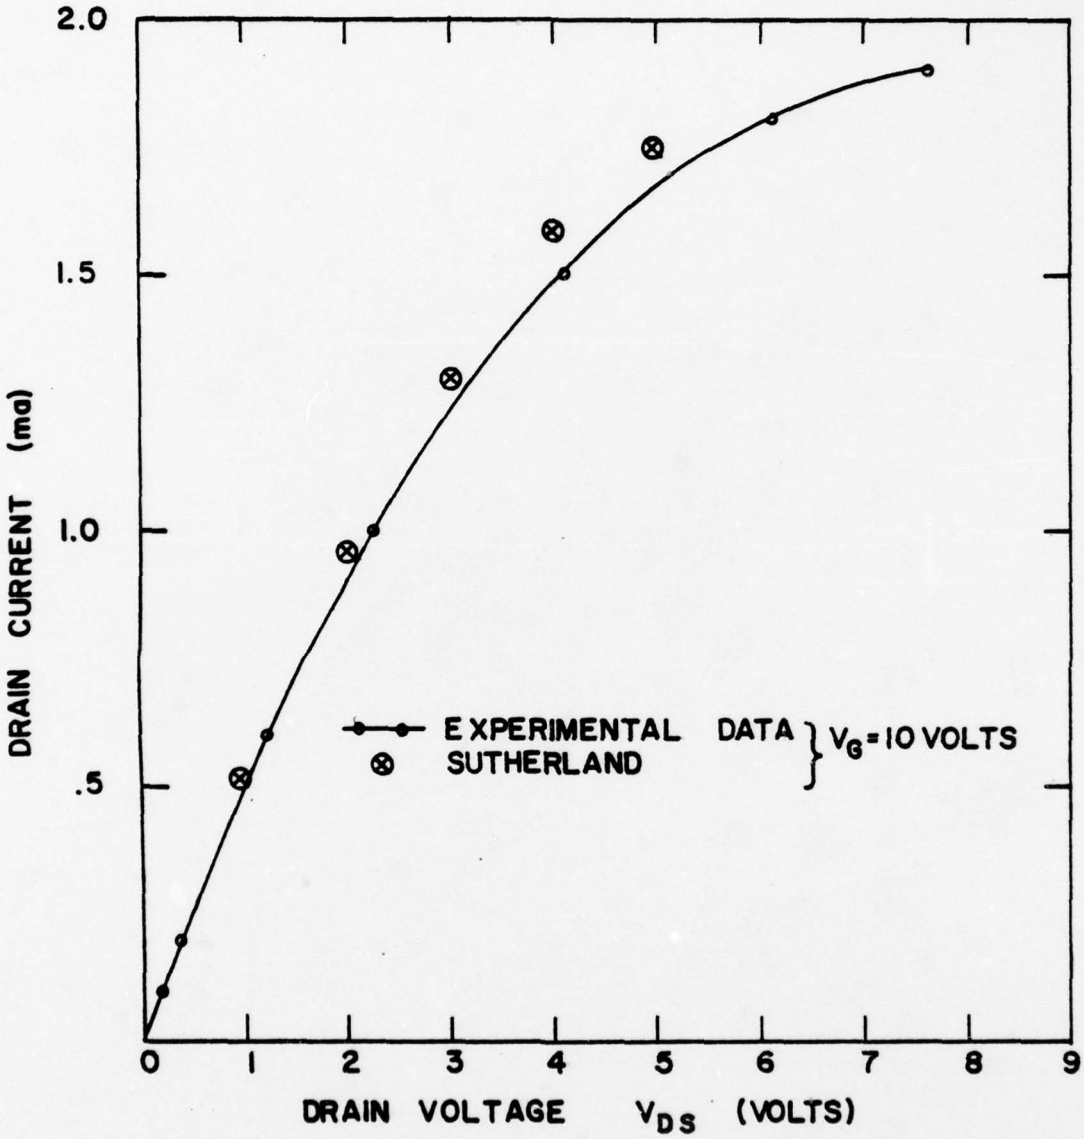

Figure 35 Comparison of the theory with experimental data obtained from a p-channel MOSFET device whose parameters were characterized by means of test sites on its chip. The curve shows I_D versus V_{DS}, with V_{GS} = 10 volts.

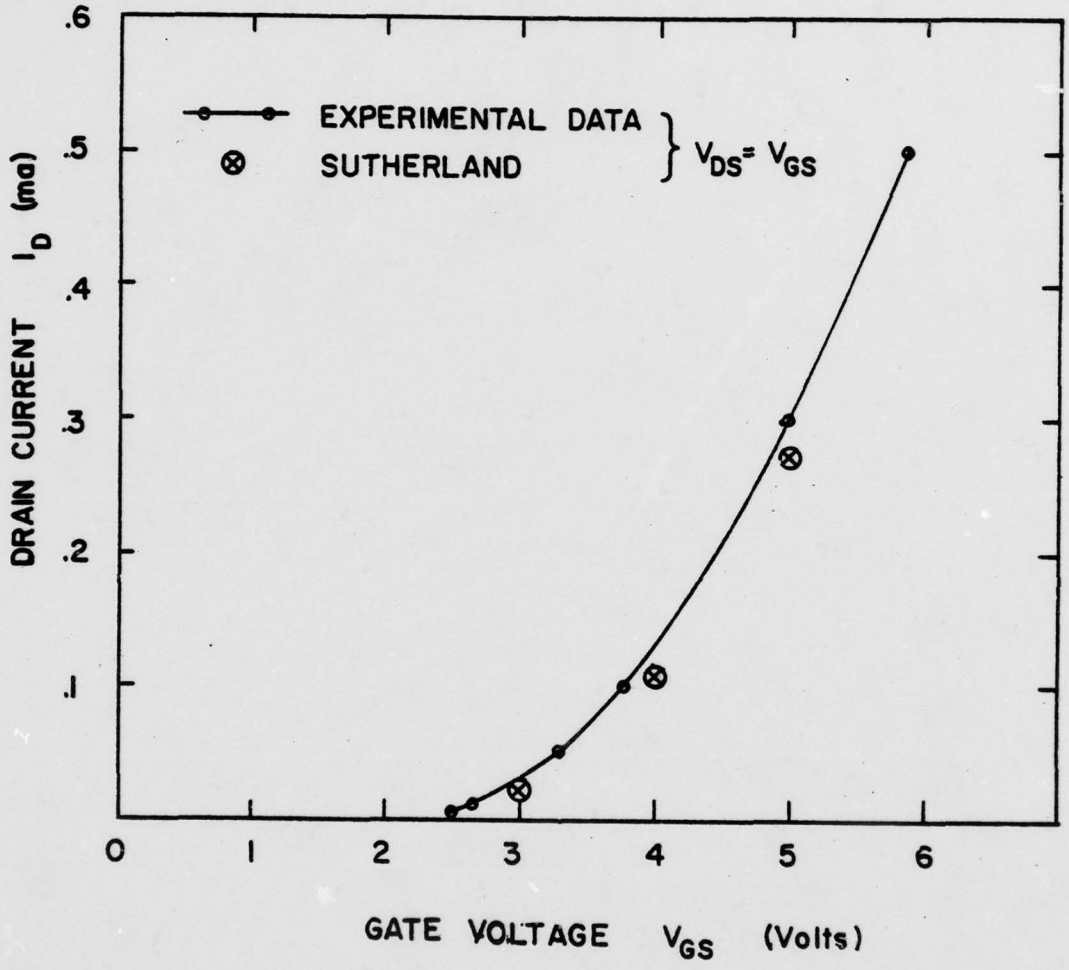

Figure 36 Comparison of the theory with experimental data obtained from a p-channel MOSFET device whose parameters were characterized by means of test sites on its chip. The curve shows I_D versus V_{GS}, with $V_{DS} = V_{GS}$.

CHAPTER III

Instructions for Using the Computer Program

1.0 Input Data

Input data for running the computer model are specified in the form of three NAMELIST data sets: NAMELIST/PRMTRS/, NAMELIST/VOLTGE/, and NAMELIST/CONTRL/. A sample input data set is given in Table III.

TABLE III -- SAMPLE INPUT DATA SET

```
&PRMTRS XCHNL=6.42,  YOXIDE=0.100, YJNCTN=0.500,  DONOR=9.07D19,
 ACCPTR=8.45D14,  QSS=-4.29D-8,  EMOB=182.0,  XDELTA=0.90,  YDELTA=0.85

            6/29/77
```

Note that the last 3 cards of the data set provide for a 3-line title by means of which the user may identify the purpose of that particular run. These 3 cards must be present in the data deck, even if left blank. Immediately following the input of these data, a listing of them is printed to provide a record for future reference.

1.01 NAMELIST/PRMTRS/

The data included in this set are:

XCHNL -- Channel length (μm)

YOXIDE -- Oxide thickness (μm)

YJNCTN -- Source and drain junction depth (μm)

DONOR -- Doping density of the source and drain (cm^{-3})

ACCPTR -- Doping density (uniform) of the p-type substrate (cm^{-3})

Q_{SS} -- Surface charge density (coul/cm^2)
EMOB -- Electron mobility (cm^2/volt-sec)
XDELTA -- Graded lattice parameter for the x coordinate
YDELTA -- Graded lattice parameter for the y cooordinate
IMAX -- # of lattice points in the x direction. This must be an odd integer $\leq$ 41
JMAX -- # of lattice points in the y direction. This can be any integer $\leq$ 25.

Regarding QSS, it is possible to account for work function differences between the gate metallization and the silicon substrate by defining an "effective" Q_{SS} given by $Q_{SS_{eff}} = C_{ox}V_{FB}$, where C_{ox} is the oxide layer capacitance, $C_{ox} \equiv \kappa_{ox}\varepsilon_o/y_{ox}$ (F/cm^2), and where V_{FB} is the flatband voltage of MOS capacitor theory.

The graded lattice parameters XDELTA and YDELTA determine the spacing between lattice points in the following manner. Let IMID by the I-index of the plane midway between the source and the drain. Let XDLT (IMID) be the spacing between that plane and the planes IMID±1 immediately to the right and left of the mid-plane. Then the algorithm for determining XDLT(I), given XDLT(IMID), is

```
XDLT(I-1) = XDELTA*XDLT(I),     I=3,IMID
XDLT(I+1) = XDELTA*XDLT(I),     I=IMID+1,IMAX-1
```

where XDELTA $\leq$ 1. The graded lattice illustrated in Figure 2, in Chapter I, was generated with XDELTA = Ø.9, the value suggested by Mock [1]. In a like manner, let YDLT(2) be the vertical lattice spacing at the substrate "contact." Then the algorithm employed for determining YDLT(J), given YDLT(2), is,

```
YDLT(J+1) = YDELTA*YDLT(J),     J=3,JMAX-1
```

where YDELTA $\leq$ 1. The graded lattice of Figure 2 was generated with YDELTA = 0.85, again the value suggested by Mock.

Note that the substrate thickness YSUB is not specified by the user. It is automatically adjusted to provide a spacing between the substrate contact and the lower edge of the source and drain "contacts" which is 50% greater than the drain space-charge layer width $W_{D_{drain}}$, calculated from abrupt junction depletion theory, and is readjusted each time the drain voltage changes. This is done to maximize the effectiveness of achieving small spacings between vertically adjacent lattice points in the vicinity of the oxide-silicon interface, while assuring charge neutrality at the substrate "contact."

1.02 NAMELIST/VOLTGE/

The data specified in this set are:

VGDLT -- Gate voltage increment (volts)
VGATEØ -- Starting gate voltage (volts)
VDDLT -- Drain voltage increment (volts)
VDRNØ -- Starting drain voltage (volts)
VSUB -- Applied substrate voltage (volts) with $V_{SUB} \leq 0$
NGATE -- # of gate voltage increments
NDRAIN -- # of drain voltage increments

The meaning of these parameters is as follows. The program has been written to function in the manner of a curve-tracer which plots families of curves of I_D versus V_{DS}, with V_{GS} varied as a parameter. The initial gate voltage is set equal to VGATEØ, and subsequent gate voltages are incremented upward in increments of VGDLT, until NGATE such voltages have been treated. The parameter NDRAIN determines the number of drain voltages at which the drain current I_D is to be determined. The lowest drain voltage used is VDRNØ. The drain voltage is then incremented upward in increments of VDDLT, until NDRAIN voltage values have been treated. The gate voltage is then incremented, and the process is repeated. During this sequence, the substrate voltage remains fixed. The user should always make an estimate of the threshold gate voltage, and specify VGATEØ $\geq V_T$.

1.03 NAMELIST/CONTRL/

The parameters in this data set provide the user a degree of control over the iteration process and, as described in Chapter I, allow him to specify whether the "Picard and Gummel" relaxation procedure devised by Mock, or the "Overrelaxed Gummel" procedure devised by the author is to be used. The parameters appearing in this data set are:

CNVRG1 -- "Coarse" and "Tight" convergence criteria for
CNVRG2 the Picard and Gummel algorithms.

SIDLT1 -- "Coarse" and "Tight" convergence criteria for
SIDLT2 Stone's method for finding ψ.

THDLT1 -- "Coarse" and "Tight" convergence criteria for
THDLT2 the Block-Line iteration for finding θ.

ITMAX -- Maximum number of iterations to be allowed with the Picard and Gummel algorithms.

ITSIMX -- Maximum number of iterations to be allowed with Stone's method.

ITTHMX -- Maximum number of iterations to be allowed with Block-Line iteration.

KRSWCH -- "Flag" to specify which iteration scheme is to be used. KRSWCH=Ø causes only Gummel's algorithm to be applied, with full donor density and "tight" convergence criteria. KRSWCH=1 causes Mock's approach to be implemented, viz. Picard iteration at reduced donor density until "coarse" convergence is achieved, followed by Gummel's algorithm at full donor density, with "tight" convergence criteria.

OMEGA -- Overrelaxation parameter used with the Gummel algorithm, as described in Section 4.03.

Table IV lists the values of the iteration control parameters which have been found to work well for gate and drain voltages $\leq$ 10 volts.*

TABLE IV -- RECOMMENDED CONTROL PARAMETERS

CNVRG1	= 3.0
CNVRG2	= .02
SIDLT1	= .01
SIDLT2	= .001
THDLT1	= .01
THDLT2	= .001
ITMAX	= 200
ITSIMX	= 100
ITTHMX	= 100
OMEGA	= 1.6

Concerning the three "maximum iterations" parameters, the program will stop, with a "MAXIMUM ITERATIONS EXCEEDED" message being printed, identifying why it stopped, in the event that this condition is encountered. These three parameters were installed by the author as "safety valves" to avoid excessive computation times when things are going awry. The author encountered program stops due to all three "safety valves" during the course of evaluating and improving the computer program and, with the exception of the "ITMAX EXCEEDED" criterion when using Mock's Picard + Gummel iterative procedure, was able to devise corrective measures to eliminate their occurrence. But the user may expect to encounter the "ITMAX EXCEEDED" exit message, especially under

*The range of gate and drain voltages explored with numerous computer runs was $V_T \leq V_G < 10V$ (V_T is the threshold gate voltage for inversion), and $1 \leq V_D \leq 9V$. The recommended value for ITMAX worked well over this range when the overrelaxed Gummel procedure was in use. However, the Picard + Gummel procedures frequently required excessive iterations, especially under conditions of strong inversion.

conditions of strong inversion, if he elects to use that procedure by setting KRSWCH=1. In the author's experience, both Stone's iterative procedure (limited by ITSIMX) and the block-line iterative procedure for the stream function (limited by ITTHMX), require only a small fraction of the "recommended" limits stated in Table IV.

2.0 Output Data

Table V (17 sheets) illustrates the output data printed by the program. A complete set of these data are printed for each pair of voltages V_G,V_D, and the user may not desire all of this data. In that event, he may wish to modify SUBROUTINE OUTPUT to suit his particular needs. Some plotting routines would also be helpful, but the author did not have sufficient time available to develop same.

All output data are listed in physical units, the conversion from normalized to unnormalized variables being implemented in SUBROUTINE OUTPUT. What these data represent will next be described.

Sheet 1 of Table V summarizes the three voltages V_G, V_D, and V_B, then gives the corresponding drain current I_D in milliamperes/cm of channel width. Next, is printed the substrate thickness which is automatically determined in the manner described above. Following this are listed in columns, the following results,

X -- The x coordinate (μm).

PSI -- The electrostatic potential at the silicon surface (volts).

PHIN -- The electron quasi-Fermi potential ϕ_n' along the row J=JMAX, just below the silicon surface.

QI -- The total inversion charge Q_i (coulombs/cm^2) at position x.

QD -- The total depletion charge Q_D (coulombs/cm^2) at position x.

YI -- The inversion layer thickness (μm) at position x.

YD -- The depletion layer thickness (μm) at position x.

Note that YI and YD are quantized because they can only be approximated, due to the quantized nature of the lattice of mesh points at which they can be determined.

The remaining data in Table V provide information about selected variables in the bulk silicon substrate. They are,

PSI(I,J) -- Electrostatic potential ψ' (volts) at the ψ-lattice points corresponding to the lattice indices (I,J). (Sheets 2 and 3)

EDENS(I,J) -- The electron density n' (cm^{-3}) at the ψ-lattice points corresponding to the lattice indices (I,J). (Sheets 4 and 5)

HDENS(I,J) -- The hole density p' (cm^{-3}) at the ψ-lattice points corresponding to the lattice indices (I,J). (Sheets 6 and 7)

THETA(I,J) -- The stream function θ (dimensionless) at the θ-lattice points corresponding to the lattice indices (I,J). (See Figure 4.) (Sheets 8 and 9)

ESUBX(I,J) -- The x-directed component of the electric field E'_x, (volts/cm) at the θ-lattice coordinates corresponding to the lattice index I, and the ψ-lattice coordinates corresponding to the lattice index J. (Sheets 10 and 11)

ESUBY(I,J) -- The y-directed component of the electric field, E'_y, (volts/cm) at the ψ lattice coordinates corresponding to the lattice index I, and the θ-lattice coordinates corresponding to the lattice index J. (Sheets 12 and 13)

JSUBX(I,J) -- The x-directed component of the electron current density, J'_x, ($amps/cm^2$) at the θ-lattice coordinates corresponding to the lattice index I, and the ψ-lattice coordinates corresponding to the lattice index J. (Sheets 14 and 15)

JSUBY(I,J) -- The y-directed component of the electron current density, J'_y, (amps/cm^2) at the ψ-lattice coordinates corresponding to the lattice index I, and the θ-lattice coordinates corresponding to the lattice index J. (Sheets 16 and 17)

In the case of Sheets 2 through 17 of Table IV, the data are formated in an identical manner. Across the top of the even numbered sheets is listed the x'-coordinate corresponding to the lattice index I. (ψ-lattice, or θ-lattice, as the case may be.) The first two columns list the lattice index J, and the corresponding y'-coordinate. (Again, ψ-lattice or θ-lattice, as the case may be.) Both coordinates are expressed in micrometers. The remaining columns give the values of the variable indicated in the legend printed just below the listing of the x'-coordinate values. One scans each horizontal group of data (correspoding to a given lattice index J) in the manner of reading a printed page. Scanning first the listing of X(I) at the top of the sheet, one finds the corresponding value of the variable of interest in the corresponding location in the listing for the value of Y(J) (Column 2). In this manner, the two-dimensional solution for these variables is obtained.

3.0 Glossary of the Variables Appearing in COMMON Statements

Five COMMON blocks are defined in the computer program: ARRAYS, COEFF, REAL, INTGR, NRMLZE. The FORTRAN variables contained therein are next defined.

3.01 COMMON/ARRAYS/

PSI(41,3Ø) -- The electrostatic potential ψ.
EDENS(41,25) -- The electron density n.
HDENS(41,25) -- The hole density p.
THETA(4Ø,25) -- The stream function θ.

B(41,3Ø)
D(41,3Ø)
E(41,3Ø)
F(41,3Ø)
H(41,3Ø)
Q(41,3Ø)
-- Stone's coefficients B,D,E,F,H, and Q. (Also used for the Block-line iteration for θ, in the same context.)

CURRENT VOLTAGE RESULT :

VG= 3.000+00 VOLTS
VD= 8.000+00 VOLTS
VB= 0.0 VOLTS
ID= -6.170-01 MILLIAMPS/CM OF CHANNEL WIDTH

SUBSTRATE THICKNESS (AUTOMATICALLY DETERMINED) IS YSUB= 1.636D+00 MICROMETERS

SUMMARY OF CONDITIONS ALONG THE SILICON-OXIDE INTERFACE :

Table V sheet 17

DELTA(41,3Ø) -- The new residual ($v^{(m+1)} - \psi^{(m)}$) calculated by Stone's method (Gummel's δ). See Sections 4.01 and 4.02 of Chapter I.

XPOS(41) - The x-coordinate corresponding to the ψ-lattice index I.

YPOS(25) -- The y-coordinate corresponding to the ψ-lattice index J.

XTHPOS(41) -- The x-coordinate corresponding to the θ-lattice index I.

YTHPOS(25) -- The y-coordinate corresponding to the θ-lattice index J.

3.02 COMMON/COEFF/

XDLT(42) -- The ψ-lattice spacing $\Delta x(I)$.

YDLT(31) -- The ψ-lattice spacing $\Delta y(J)$.

XTHDLT(41) -- The θ-lattice spacing $\tilde{\Delta}x(I)$.

YTHDLT(25) -- The θ-lattice spacing $\tilde{\Delta}y(J)$.

HNRTH(41,30) -- The "north" coefficient $\tilde{\Delta}x(I)/\Delta y(J+1)$, appearing in eq. (23) as H_p.

HEAST(41,30) -- The "east" coefficient $\tilde{\Delta}y(J)/\Delta x(I+1)$, appearing in eq. (23) as F_p.

HSTH(41,30) -- The "south" coefficient $\tilde{\Delta}x(I)/\Delta y(J)$, appearing in eq. (23) as B_p.

HWEST(41,30) -- The "west" coefficient $\tilde{\Delta}y(J)/\Delta x(I)$, appearing in eq. (23) as D_p.

HCNTR(41,30) -- The "center" coefficient appearing in eq. (23) as E_p.

THNRTH(4Ø,25) -- The "north" coefficient $-\Delta x(I+1)/\tilde{\Delta}y(J+1)$ appearing in eq. (40). (The minus sign is used to make the matrix involved in the block-line iteration for θ positive-definite -- a crucial factor for convergence of that iterative scheme.)

THEAST(4Ø,25) -- The "east" coefficient $-\Delta y(J+1)/\tilde{\Delta}x(I+1)$ appearing in eq. (40). (Same reason for the minus sign.)

THSTH(4Ø,25) -- The "south" coefficient $-\Delta x(I+1)/\tilde{\Delta}y(J)$ appearing in eq. (40). (Same reason for the minus sign.)

THWEST(4Ø,25) -- The "west" coefficient $-\Delta y(J+1)/\tilde{\Delta}x(I)$ appearing in eq. (40). (Same reason for the minus sign.)

QAREA(41,25) -- The area $\tilde{\Delta}x(I)\tilde{\Delta}y(J)$ associated with the ψ-lattice point (I,J), for purposes of calculating the charge contained within that "box."

3.03 COMMON/REAL/

XCHNL -- The channel length (spacing between the source and drain "contacts" in the x-direction).

YSUB -- The substrate thickness in the y-direction.

YOXIDE -- The oxide thickness.

YJNCTN -- The source and drain junction depths in the y-direction.

DONOR -- The donor density in the source and drain.

ACCPTR -- The acceptor density in the substrate region (assumed independent of x and y).

VGATE -- The applied gate voltage.

VSUB -- The applied substrate (back gate) voltage (assumed always to be negative, or zero).

VDRAIN -- The applied drain voltage.

DIELK -- The ratio of dielectric constants (κ_{ox}/κ_{si}).

QSS -- The surface charge density at the oxide-silicon interface. (This can account for the metal-oxide work function difference ϕ_{MS}, as discussed in Section 1.01 of this chapter.)

CURRNT -- The drain current factor J_o discussed in Section 2.05 of Chapter I.

EDENSØ -- The electron density n in the charge-neutral region of the silicon substrate.

PSIEQ -- The electrostatic potential of the charge-neutral region of the substrate (PSIEQ = $-\ell n(N_D N_A) + V_{SUB}$).

3.04 COMMON/INTGR/

IMAX -- Maximum of the index I definiting the x-coordinate.

JMAX -- Maximum of the index J defining the y-coordinate within the silicon substrate.

JMAX5 -- Maximum of the index J defining the y-coordinate within both the silicon substrate and the oxide region (JMAX5 = JMAX + 5).

JUNCTN -- The J index which defines the lower corner of the source and drain "contacts."

ITHMAX -- Maximum of the index I for the θ-lattice (ITHMAX = IMAX - 1).

3.05 COMMON/NRMLZE/

DNSNRM -- Electron and hole density normalization parameter.
PSINRM -- Electrostatic potential normalization parameter.
DEBYE -- Intrinsic Debye length.
QNORM -- Surface charge normalization parameter.
CRTNRM -- Current density normalization parameter.

3.06 COMMON/CNTRL/

OMEGA -- The overrelaxation parameter Ω used for over-relaxation with Gummel's algorithm.

CHAPTER IV

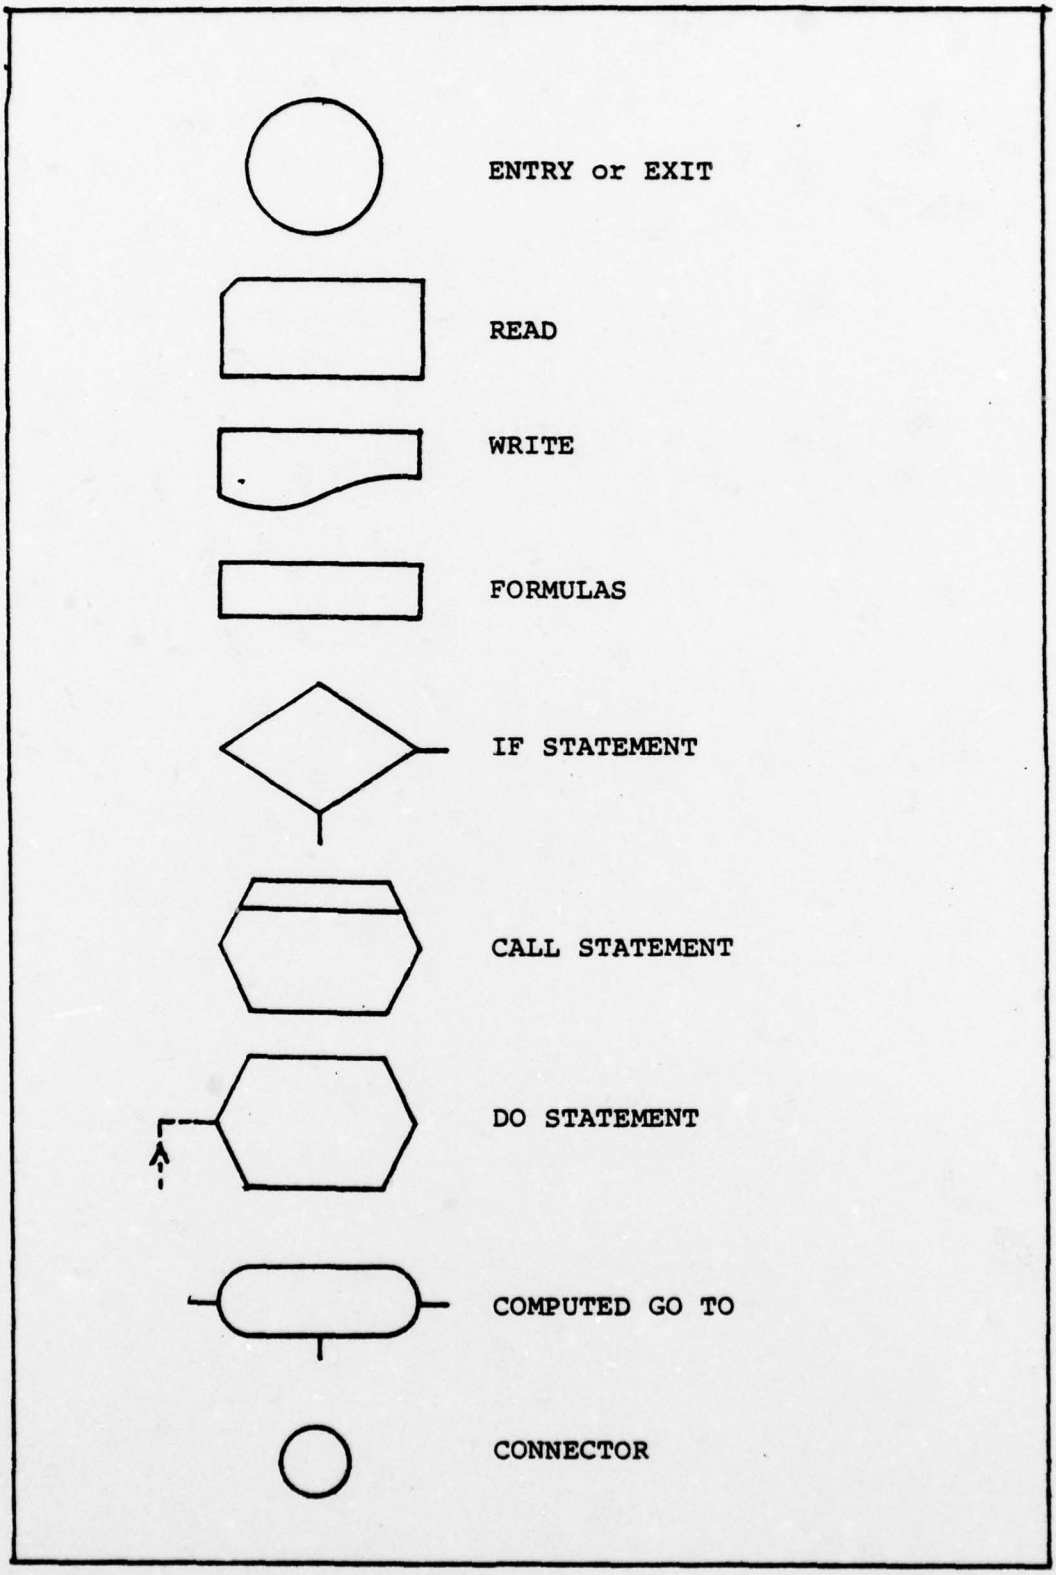
Program Listing, with Flowcharts

With the 41x30 ψ-lattice dimensions specified in the DIMENSION statements incorporated in the program, roughly 336,000 Bytes of core storage are required. The program consists of a main executive program, together with 21 FUNCTION and SUBROUTINE subprograms. (Two of the subprograms, GRELAX, and STONE) are embedded as ENTRY statements in other subprograms, viz. RELAX and STONE.)

Each subprogram is liberally sprinkled with COMMENT statements which, together with the flowcharts provided herein should make the functioning of that subprogram fairly transparent to a reader skilled in FORTRAN IV. We have consistently operated the program using IBM's Level H Extended, Optimization 2, Compiler.

In this chapter, section by section, we provide a brief description of each subprogram, together with a listing, and detailed flowcharts. Regarding the latter, Table VI defines the convention adopted for displaying the various FORTRAN operations in graphic form.

TABLE VI -- SYMBOLS APPEARING IN THE FLOWCHARTS



1.0 MAIN

This is the executive program which controls the functioning of the overall program. It reads the input data in unnormalized form, records them for future reference by the user, normalizes them, then controls the sequence of operations required to trace out characteristic curves of I_D versus V_{DS}, with V_{GS} varied as a parameter. By means of the parameter KRSWCH, it implements either Mock's iterative procedure -- Picard iteration at reduced donor density for coarse convergence, followed by Gummel's algorithm, with full donor density for tight convergence -- or Gummel's algorithm throughout.

MAIN SHEET 1 of 1

2.0 GRID

This subprogram establishes the ψ and θ-lattice spacings $\Delta x(I)$, $\Delta y(J)$, $\tilde{\Delta} x(I)$, $\tilde{\Delta} y(J)$, following the procedure devised by Mock [1] for generating the graded lattice illustrated in Figure 2 of Chapter I. It then calculates the finite-difference coefficients required in the implementation of Stone's method and of Block-Line iteration. The special procedures for treating the boundary conditions at the oxide-silicon interface, described in Chapter I, Section 3.01.1, are implemented in this subprogram.

3.0 BORDER

This subprogram assigns the boundary conditions on ψ, n, and p at the borders of the lattice. Since the substrate potential ($\psi_{SUB} = -\ell n(N_D N_A) + V_{SUB}$) depends upon the donor density N_D, and since the latter is generally a reduced value if the Picard iteration method has been used (i.e., if Mock's iterative procedure is being employed) it is necessary to shift the level of the array PSI(I,J), as determined from convergence of the Picard iteration, to account for the increased donor density which will next be used for Gummel's algorithm. This is done by BORDER, the flags KRSWCH and KDOPE determining whether this is necessary.

4.0 NITIAL

This subprogram calculates the initial estimates for $\psi(x,y)$ and $\theta(x,y)$. It first assigns $\psi = -\ell n(N_D N_A) + V_{SUB}$ throughout the silicon substrate, then overwrites this with the potential determined from depletion theory to create space-charge "sheaths" in contact with the source and drain. (An interpolation scheme is applied to provide smooth transitions in the corner regions at the lower edges of the source and drain "contacts.") This procedure establishes $\psi_B(x)$ -- the curve shown dotted in Figure 10(b). The Kennedy-Murley-Motta equations are then used to determine the potential $\psi_s(x)$ along the oxide-silicon interface for $0<x<(x_{channel} - 1.3W_{D_{drain}})$, with a parabolic equation extending $\psi_s(x)$ beyond that point in the manner described in Chapter I, Section 4.04.1. Then, given $\psi_s(x)$ and $\psi_B(x)$, one-dimensional solutions of Poisson's equation for $\psi(y)$ are generated vertically downward from the interface, matching $\psi_B(x)$, with zero $d\psi/dy$, deep within the substrate, and matching $\psi_s(x)$ at the interface. For each such vertical solution, the electron quasi-Fermi level ϕ_n (assumed not to vary with y in these one-dimensional solutions) is adjusted to satisfy the boundary condition on $d\psi/dy$ which must be satisfied at the oxide-silicon interface. The potential within the oxide region is approximated to vary linearly with y, matching $\psi = \psi_s(x)$ at the interface, and $\psi = \psi_{gate}$ at the gate contact.

The initial estimate for $\theta(x,y)$ uses the one-dimensional parabolic estimate discussed in Chapter I, Section 4.04.2, established along the vertical plane corresponding to the edge of the space-charge sheath adjacent to the source.

5.0 VZERO & DERIV

FUNCTION VZERO solves a transcendental equation for the surface potential V_o of the Kennedy-Motta-Murley theory. (This is the result of a one-dimensional solution of Poisson's equation in y which assumes that equilibrium conditions, viz. $\phi_n = \phi_p$, apply close to the source, as in MOS capacitor theory.) The subprogram uses the method of secants [14] to achieve this, and implicitly assumes that the energy band bending will always be in the direction which causes inversion at the silicon surface. Thus, when attempting to model p-channel structures by using this n-channel model (as was described in Chapter III) the user must assure that the above condition is not violated. Otherwise, an error message will be printed and the run will terminate.

FUNCTION DERIV provides the derivatives $d\psi/dy$ required by ONEDIM, which generates the one-dimensional solutions for $\psi(y)$ needed in implementing NITIAL, as discussed in the preceeding section.

FUNCTIONS VZERO & DERIV SHEET 1 Of 1

6.0 ONEDIM

This subroutine implements the Adams-Bashforth-Moulton predictor-corrector algorithm [15], with a simple modification to improve its accuracy [16], to obtain the one-dimensional solutions of Poisson's equation required for NITIAL. It utilizes a 4th order Runge-Kutta starting procedure [17] to initialize the solution. Interval halving and doubling are invoked when tests show that these measures are acceptable.

7.0 RELAX & GRELAX

This subprogram implements the Picard iteration method described in Chapter I, Section 4.01. It calculates and applies the Chebyscheff sequence of relaxation parameters, reinitiating said sequence whenever the maximum residual at step (m+1) is detected to exceed that encountered at step (m), as suggested by Mock.

7.01 GRELAX

GRELAX, which appears as an ENTRY statement in RELAX (in order to reduce storage requirements because it utilizes some arrays also used by RELAX), implements the overrelaxed Gummel's algorithm, described in Chapter I, Section 4.02.

8.0 STREAM

This subprogram solves for the stream function $\theta(x,y)$, and controls the Block-Line iteration algorithm until convergence is achieved. Given the potentials at the four ψ-lattice points NE, SE, SW, and NW of the θ-lattice point under consideration, it selects the one of 16 possible cases which assures that only negative exponents will be encountered in the operation DEXP(x), and that only differences in potential between adjacent ψ-lattice points will appear as such exponents. It calls subroutine BLOCK, each iteration, to implement the algorithm. It calls upon function programs SIFUNC and EXPFNC to evaluate exponential functions which supply, in turn, appropriate approximations when exponential underflow, or division by zero operations are imminent.

12.0 EIGEN

This subprogram evaluates the upper and lower bounds, b and a, of the eigenvealues of equation (24), the finite-difference equation for ψ described in Chapter I, Section 4.01. The lower bound, a, is set to unity, since its value is not critical for the Picard iteration. The upper bound, b, is evaluated from eq. (54), using a two-dimensional trapezoidal rule to approximate the integral contained therein.

14.0 STONE & STONE1

This subprogram implements Stone's method for determining $\psi(x,y)$, given the charge term $\rho(x,y)$ in Poisson's equation. The iterative scheme necessary is controlled by subroutine POISSN. This particular subprogram uses a notation which deviates from the notation utilized in other subprograms to make it more transparent to those who study Stone's paper [7]. For example, the indices (I,J) used elsewhere become (J,K), as defined by Stone. Similarly, the potential $\psi(x,y)$ used elsewhere becomes T(x,y), since Stone discusses solving Poisson's equation in the context of a heat flow problem. The variables AA, BB, etc., represent Stone's a, b, etc. The intention in doing this was to make STONE a "utility" program which can be extracted and used in other situations by those who wish to implement Stone's method for their purposes.

14.01 STONE1

This subprogram, which appears as an ENTRY statement in STONE, implements Stone's suggested sequence of his relaxation parameters, α, and initializes the arrays which are internal to STONE. Some of the notation utilized here (e.g., XCHHL, (YSUB+YOXIDE), JMAX5) would require revision were the reader desirous of extracting STONE for use as a "utility" program.

15.0 CHARGE

This subprogram calculates the charge term Q_p defined in eq. (23) of Chapter I, Section 3.01.2, using eq. (36) if the Picard iterative procedure is in use. As explained in Section 4.02 of Chapter I, it invokes appropriate modifications of both Q_p and E_p, in eq. (23), if Gummel's algorithm is in use. These procedures are almost trivial, and hardly call for a separate subroutine for their implementation. The fact that Subroutine CHARGE exists as such is a vestige of the fact that, at one time during the development, more elaborate procedures for calculating Q_p were tried; procedures which were ultimately found unnecessary.

CHARGE SHEET 1 of 1

16.0 OUTPUT

This subprogram performs the obvious function of providing for the printing of output data concerning the solution. It should be transparent to the user, and is the one subprogram which he is most likely to wish to modify to suit his own needs. About the only aspect of OUTPUT that needs clarification is the method used to calculate the inversion charge QI, and the depletion charge QD. In both instances, piece-wise exponential "fits" are utilized to approximate the electron and hole densities as a function of the vertical coordinate y between adjacent lattice points, and an analytic evaluation of the integrals required for those parameters is applied. No flowchart for OUTPUT is included herein, because it is deemed unnecessary.

```

CHAPTER V
Conclusions

The two-dimensional model for an MOSFET described herein has proven to produce results in good agreement with those of the predecessor program developed by Mock. A single check with an experimental p-channel structure, whose parameters have been well characterized by means of "test sites" has also shown good agreement with experiment.

It has been found that Gummel's iterative algorithm, when overrelaxed, proves to be impressively efficient in terms of rate of convergence, when compared with Mock's, Picard and Gummel procedure. The author is unaware of instances in which such overrelaxation procedures have been previously used for solving the nonlinear equations involved with semiconductor devices, although they have been widely used for the equations encountered with vacuum tube devices. In view of the success of this approach, further investigations of the procedure, in the interest of optimization of convergence rates would appear desirable.
